Glossary

Aptamer An RNA or DNA molecule that has been evolved to bind specifically to a small molecule, another nucleic acid, or a protein.

Ribonucleoprotein (RNP) Supramolecular complex formed by association of RNA and protein molecules.

Riboswitch Domain in a messenger RNA (mRNA) that regulates the expression of the mRNA in response to specific binding of a regulatory small molecule.

Ribozyme An RNA molecule that functions as an enzyme and catalyzes specific biochemical reactions.

RNA world hypothesis A proposition that at an early stage in the evolution of life, RNA molecules served as both,

repositories of genetic information, and biochemical catalysts.

Systematic evolution of ligands by exponential enrichment (SELEX) A technique for isolating DNA or RNA sequences with functional properties from a population of nucleic acid molecules.

Viroid Plant pathogens that consist solely of a short, circular, single-stranded RNA.

Virusoid Infectious agents composed of circular, single-stranded RNAs that require assistance from other viruses for replication and propagation.

Evolutionary Importance of RNA

Evolution of all organisms, from unicellular archaea and bacteria to multicellular eukaryotes, requires the inheritance of genetic information. In modern cell-based biology, this information is encoded in DNA and directs the synthesis of cellular proteins through RNA (many viruses use RNA as the repository for genetic information). Although RNA was thought, early on, to act primarily as a conduit of information between DNA and proteins, already in 1961 Jacob and Monod proposed that some RNAs might function directly in genetic regulation by sensing the intracellular concentration of small molecule metabolites (Jacob and Monod, 1961). The description of the secondary structure of tRNA by Holley and colleagues in 1965 suggested that RNAs can adopt complex three-dimensional structures resembling those of proteins (Holley *et al.*, 1965). Such proposals, and central roles played by RNA in the synthesis of proteins in contemporary cells, led Crick and Orgel to hypothesize in 1968 that at an early stage in the evolution of life, RNAs could have served both as carriers of genetic information and as genetically encoded catalysts (Orgel, 1968; Crick, 1968).

Catalytic RNAs: Ribozymes

Important support for this 'RNA world hypothesis' came from the discovery in the early 1980's of enzymes made entirely of RNA, or ribozymes (Table 1). The first two classes of ribozymes described were the self-splicing 'group I' introns (Kruger *et al.*, 1982), and the tRNA precursor processing enzyme, ribonuclease (RNase) P (Guerrier-Takada *et al.*, 1983). The ability of RNA to catalyze chemical reactions provided strong evidence that some RNAs, just like protein enzymes, can adopt complex three-dimensional structures that can precisely position reactants and catalytic functional groups, and preferentially stabilize transition states. Since the initial discovery of ribozymes, much work has been devoted to examining the

ability of RNAs to catalyze metabolic reactions, both in contemporary cells and in putative pre-biotic metabolisms.

In Vitro Selection of Aptamers and Ribozymes

A powerful technique for the discovery and characterization RNAs that have intrinsic biochemical functions is *in vitro* selection, or SELEX. In the late 1980s, the groups of Gold, Joyce and Szostak invented this methodology, which consists of subjecting a pool of RNAs of diverse sequence (pools comprising as many as $\sim 10^{15}$ different sequences are employed) to a selective pressure, and amplifying the most active species (Joyce, 1989; Ellington and Szostak, 1990; Tuerk and Gold, 1990). The process is iterated until a handful of RNAs that are very efficient in the activity for which they are being selected is obtained. This process, which mimics Darwinian evolution, was initially used to obtain RNA molecules capable of high affinity and specificity binding to small molecules. Such RNAs were named 'aptamers.' Since then, SELEX has been used to isolate many different aptamers, which bind selectively to a variety of ligands ranging from simple ions to large proteins. In addition, SELEX has been used to isolate ribozymes with new activities. Unlike catalytic antibodies, which are typically selected for tight binding to transition-state mimics, SELEX for ribozymes has been most successful by searching for RNA molecules capable of catalyzing the desired chemical transformation on themselves, or a covalently bound substrate. *In vitro* selection has led to the isolation of RNAs capable of catalyzing a broad range of chemical transformations, greatly expanding the known chemical versatility of this nucleic acid (Table 2).

From Aptamers to Riboswitches

Even though the sequence pools employed for SELEX are very complex, they typically only cover a minuscule fraction of the

Table 1 Natural ribozymes

Ribozyme	Bond formation	Reaction	Functional groups in reaction	k_{obs} (min^{-1})	References
Hammer-head	P–O	Transesterification (self-cleavage)	2'-OH of RNA, internal RNA phosphate	~ 10 (~ 200 at 200 mM Mg^{2+})	Canny <i>et al.</i> (2004)
HDV/CPEB3	P–O	Transesterification (self-cleavage)	2'-OH of RNA, internal RNA phosphate	$> 60/0.01$	Thill <i>et al.</i> (1993)
Hairpin	P–O	Transesterification (self-cleavage)	2'-OH of RNA, internal RNA phosphate	~ 0.5	Hegg and Fedor (1995)
VS	P–O	Transesterification (self-cleavage)	2'-OH of RNA, internal RNA phosphate	~ 1 (~ 600 for mutant)	Zamel <i>et al.</i> (2004)
<i>glmS</i> ribozyme	P–O	Transesterification (self-cleavage)	2'-OH of RNA, internal RNA phosphate	~ 70	Lau and Ferre-D'Amare (2013)
Twister	P–O	Transesterification (self-cleavage)	Internal 2'-OH of RNA, internal RNA phosphate	Est. ~ 1000	Roth <i>et al.</i> (2014)
CoTC	P–O	Transesterification (self-cleavage)	Internal 2'-OH of RNA, internal RNA phosphate	~ 0.015	Teixeira <i>et al.</i> (2004)
Ribosome	C–N	Peptidyl transfer	α -amine of amino acid, carbonyl of peptidyl-RNA	up to 3000	Katunin <i>et al.</i> (2002)
Group I intron	P–O	Splicing (2 steps)	2'-OH of internal RNA adenosine (or OH ⁻), internal RNA phosphate, 3'-OH of RNA	~ 1	Bass and Cech (1984)
Group II intron	P–O	Splicing (2 steps)	2'-OH of guanosine (or OH ⁻), internal RNA phosphate, 3'-OH of RNA	~ 0.1	Xiang <i>et al.</i> (1998)
GIR 1	P–O	Transesterification (branching)	Internal 2'-OH of RNA, internal RNA phosphate	~ 0.3	Tang <i>et al.</i> (2011)
RNAse P	P–O	Transesterification (cleavage)	OH ⁻ ion (proposed), internal RNA phosphate	~ 300	Beebe and Fierke (1994)

Table 2 Examples of artificially selected ribozymes

Ribozyme	Bond formation	Reaction	Functional groups in reaction	k_{obs} (min^{-1})	References
Class I Ligase	P–O	Ligation	3'-OH of RNA, 5' α -phosphate of RNA	60 (~ 800 at pH 9)	Glasner <i>et al.</i> (2002)
Class II Kin.25	P–O	Phosphorylation	5'-OH of RNA, 5' γ -thio-phosphate of γ -thio-ATP	~ 0.3	Lorsch and Szostak (1994)
Iso6	P–O	Capping	5' β -phosphate of GDP, 5' α -phosphate of RNA	0.08	Huang and Yarus (1997)
Leadzyme	P–O	Transesterification, Hydrolysis (2 steps)	2'-OH of RNA, internal RNA phosphate	~ 0.5	Pan and Uhlenbeck (1992)
CoES7	P–O	Adenylation	Phosphate of NMN/FMN / 4'-phosphopantetheine, 5' α -phosphate of RNA	0.060	Huang <i>et al.</i> (2000)
DA-22	C–C	Diels–Alder	C–C double bond of maleimide, C–C double bond of anthracene	~ 0.7	Seelig and Jäschke (1999)
Clone 10	C–C	Claisen condensation	Acyl group of acyl-coenzyme A, carboxyl group of malonyl	N/A	Ryu <i>et al.</i> (2006)
Pre-24	C–O	Aminoacylation	3'-OH of tRNA, carbonyl of amino acids	0.15	Saito <i>et al.</i> (2001)
RA, MA	C–N	Glycosidic bond formation	N7 of 6-thioguanine, C1 of 5-phosphoribosyl 1-pyrophosphate	0.02	Lau <i>et al.</i> (2004)
pR1	C–N	Schiff base	N7 of 6-thioguanine, aldehyde of ribose-5-phosphate	0.001	Lau and Unrau (2009)
UV5	C–S	Michael addition	Sulfhydryl group, C–C double bond of fumaramide	0.01	Sengle <i>et al.</i> (2001)

total possible number of sequences for a given RNA length. For instance, for a 50-nucleotide long RNA, there are $\sim 1.3 \times 10^{30}$ possible unique sequences (4^{50}). Nonetheless, aptamers

targeting a variety of ligands can be found quite readily. This implies that biochemically active RNA species are relatively common in RNA 'sequence space.' In turn, such abundance

suggests that aptamer-like RNAs may exist in contemporary cells. Indeed, the T-box, a first example of such an RNA, was discovered in 1993 (Grundy and Henkin, 1993). This is a structured domain that lies in the 5' untranslated region (UTR) of mRNAs encoding aminoacyl-tRNA synthetases (ARSs) and is conserved across Gram-positive bacteria (Miranda-Ríos *et al.*, 2001). T-boxes bind sequence-specifically to a tRNA (engaging its anticodon), and control the expression of the mRNA they are part of depending on whether the tRNA is charged with its cognate amino acid (i.e., aminoacylated) or not. In this way, this cellular aptamer can respond with a gene expression decision to starvation for a particular amino acid. Many naturally occurring aptamer-like domains of mRNA that control gene expression *in-cis* by directly binding to their cognate intracellular ligands have been discovered in the present century (Mironov *et al.*, 2002; Nahvi *et al.*, 2002; Serganov and Nudler, 2013). Such RNA genetic switches, or 'riboswitches' are now known to respond selectively to simple ions (fluoride and magnesium), amino acids (glycine and lysine), vitamins and other enzymatic cofactors (adenosine cobalamine, flavin mononucleotide, thiamine pyrophosphate (TPP) and S-adenosyl methionine (SAM)), second messengers (cyclic-di-GMP), etc. For some ligands such as SAM, riboswitches appear to have evolved multiple times, independently; sequence and crystallographic analysis reveals the existence of at least four structurally distinct classes of SAM riboswitches. At the time of writing, there are 28 known riboswitch classes that collectively respond to 22 different ligands (Table 3). Although examples of the TPP riboswitch have been found to function in plants, fungi and archaea, the vast majority of currently characterized riboswitches appear to be exclusively bacterial. Whether this distribution is a true indication of the under-representation of gene-regulatory aptamers in eukarya, or reflects biases in the bioinformatic, genetic and biochemical methodology employed thus far to discover riboswitches, remains to be established.

Control of Gene Expression by Riboswitches

By definition, all riboswitches are capable of high specificity binding to their cognate ligand. However, the mechanisms by which they transduce the initial binding event into a gene-regulatory decision vary, even among different examples of riboswitches from the same structural class. At present, riboswitches are known to control expression of genes in five different ways (Figure 1): (1) Many bacterial riboswitches function by adopting alternate conformations that result in the stabilization or destabilization of an intrinsic (p -independent) transcriptional terminator (Serganov *et al.*, 2008). Such terminators consist of a stable stem-loop followed by several uridine residues, and riboswitches can, for instance, form a structure that sequesters one of the strands of the terminator stem-loop into their ligand binding-stabilized aptamer domain structure. In such an example, the riboswitch would function as a transcriptional 'on' switch. Transcriptional 'off' switches are also legion. (2) Riboswitch-mediated transcriptional termination, as just described, gives rise to a truncated transcript encompassed by the transcriptional initiation and termination sites. In some instances, these short RNAs have

been found to function in *trans*-, that is, by binding to other mRNAs and controlling their expression, analogous to the way that bacterial sRNA or eukaryal miRNA function (Loh *et al.*, 2010). (3) Riboswitches can adopt alternate conformations as a function of ligand binding that expose or occlude the Shine-Dalgarno (ribosome-binding) site of the mRNA of which they are part (Serganov *et al.*, 2009). Depending on which conformation of the 5'-UTR is stabilized by ligand binding, such riboswitches can be translational 'on' or 'off' switches. (4) The *glmS* ribozyme-riboswitch is a catalytic RNA that cleaves the 5'-UTR of the mRNA it is part of in response to ligand binding (Klein and Ferre-D'Amare, 2006). This cleavage leads to rapid degradation of the mRNA. Thus, this is one example where gene expression is regulated at the level of mRNA decay by a riboswitch. (5) Several examples of plant and fungal TPP riboswitches are known to control alternative pre-mRNA splicing, by exposing splice enhancer sequences as a function of ligand binding (Li and Breaker, 2013). Some bacterial Class-II cyclic-di-GMP riboswitches also function by modulating alternative splicing, in this case, of a self-splicing group I intron with which they are tightly coupled structurally. This mechanistic diversity (likely to be expanded by future discoveries), coupled with the versatility of RNA in specifically recognizing diverse ligands, underpins the widespread use of riboswitches as genetic regulators.

Ribozymes are Ubiquitous in Nature

Ribozymes are found in all living organisms, where they catalyze peptide bond formation or phosphoryl transfer reactions. Crick speculated that the primordial ribosome would have been a catalytic RNA (Crick, 1968), and biochemical and structural analyses in the past twenty years have demonstrated that the enzymatic active site of modern ribosomes is indeed constructed exclusively of RNA. That is, the ribosome is a ribozyme (Ban *et al.*, 2000). Many eukaryotic genes are interrupted by noncoding elements called introns. Some introns harbor catalytic activity, and are capable of self-splicing. Two major structural classes of such introns (group I and group II) have been extensively characterized. Some of these have been demonstrated to be selfish mobile genetic elements. The biochemical mechanism and structure of group II introns resembles those of the RNA components of the spliceosome, the *trans*-acting ribonucleoprotein (RNP) that excises most introns in eukaryotes. Thus, it is thought that the active site of this large RNP, like that of the ribosome, consists exclusively of RNA. Further structural studies will be needed to confirm this hypothesis. RNase P is responsible for excising the universal 5' leader sequence that must be removed for tRNA maturation. In virtually all organisms, RNase P is an RNP with an all-RNA active site. At least six structurally distinct classes of RNA-cleaving ribozymes that share an internal transesterification mechanism have been described, and these play key roles in gene regulation in bacteria, in eukaryotes, as well as in subgenomic elements such as viroids and virusoids. Despite their wide distribution and abundance (the ribosome is the most abundant particle, by mass, in an actively growing yeast), naturally occurring ribozymes are known to catalyze only a limited subset of the reactions that RNA has been shown to be

Table 3 Natural riboswitches

Riboswitch (organism)	Ligand bound	K _d (nM)	Tertiary structure	Accession PDB code	References
M-box riboswitch (<i>Bacillus subtilis</i>)	Magnesium ion	$\sim 2 \times 10^6$	3 parallel helices, 2 coaxial stacks	2QBZ	Dann <i>et al.</i> (2007)
Fluoride riboswitch (<i>Thermotoga petrophila</i>)	Fluoride ion	$\sim 1.5 \times 10^5$	2 helical stems, 1 pseudoknot	4ENC	Ren <i>et al.</i> (2012)
Moco riboswitch (<i>Escherichia coli</i>)	Molybdenum	N/A	N/A	N/A	Regulski <i>et al.</i> (2008)
Tuco riboswitch (<i>E. coli</i>)	Tungsten	N/A	N/A	N/A	Regulski <i>et al.</i> (2008)
THF riboswitch (<i>Streptococcus mutans</i>)	Tetrahydrofolate/7-deazaguanine	1.8×10^4 / 2.5×10^4	5 helices, 2 coaxial stacks, a 3-way junction, 1 pseudoknot	3SD1	Trausch <i>et al.</i> (2011)
add A-riboswitch (<i>Vibrio vulnificus</i>)	Adenine/2,6-diaminopurine	300/10	3 helices, a 3-way junction	1Y26	Serganov <i>et al.</i> (2004)
xpt G-riboswitch (<i>B. subtilis</i>)	Guanine/hypoxanthine	5/50	3 helices, a 3-way junction	1Y27	Serganov <i>et al.</i> (2004)
Type IA dG riboswitch (<i>Mesoplasma florum</i>)	2' deoxyguanosine	80	3 helices, a 3-way junction	3SKI	Pikovskaya <i>et al.</i> (2011)
Pre-Q ₁ -I (<i>B. subtilis</i>)	7-aminomethyl-7-deazaguanine	20	3 helices, 1 coaxial stack, H-type pseudoknot	3FU2	Klein <i>et al.</i> (2009)
Pre-Q ₁ -II (<i>Lactobacillus rhamnosus</i>)	7-aminomethyl-7-deazaguanine	18	4 helices, 1 coaxial stack, a 3-way junction, H-type pseudoknot	4JF2	Liberman <i>et al.</i> (2013)
C-di-AMP riboswitch (<i>B. subtilis</i>)	Cyclic di-adenosine monophosphate	≤ 0.1	N/A	N/A	Nelson <i>et al.</i> (2013)
C-di-GMP riboswitch-I (<i>Vibrio cholerae</i>)	Cyclic di-guanosine monophosphate	~ 1	H-shaped, 3 helices, 1 coaxial stack, a 3-way junction	3IWN	Kulshina <i>et al.</i> (2009)
C-di-GMP riboswitch-II (<i>Clostridium acetobutylicum</i>)	Cyclic di-guanosine monophosphate	~ 1	4 helices, 1 coaxial stack, a 3-way junction, 1 pseudoknot	3IRW	Smith <i>et al.</i> (2011)
Glycine riboswitch (<i>Vibrio cholerae</i>)	Glycine	1300	3 helices, 1 coaxial stack formed from central loop	3OWI	Huang <i>et al.</i> (2010)
Lysine riboswitch (<i>Thermotoga maritima</i>)	Lysine	1800	5 helices, 2 coaxial stacks, a 5-way junction	3DIL	Serganov <i>et al.</i> (2008)
Glutamine riboswitch (<i>Synechococcus elongates</i>)	L-Glutamine	6×10^5	N/A	N/A	Ames and Breaker, (2011)
RFN element (<i>Fusobacterium nucleatum</i>)	Flavin mononucleotide	12	6 helices, a 6-way junction	3F2Q	Serganov <i>et al.</i> (2009)
SAH riboswitch (<i>Ralstonia solanacearum</i>)	S-adenosyl-homocysteine	1350	3 helices, 1 coaxial stack, H-type pseudoknot	3NPQ	Edwards <i>et al.</i> (2010)
S-box (SAM I) riboswitch (<i>Thermoanaerobacter tengcongensis</i>)	S-adenosyl-methionine	1350	4 helices, 2 coaxial stacks, a 4-way junction	2GIS	Montange and Batey (2006)
SAM II riboswitch (from <i>Sargasso Sea metagenome</i>)	S-adenosyl-methionine	670	3 helical regions, 2 loop regions, 1 coaxial stack, H-type pseudoknot	2QWY	Gilbert <i>et al.</i> (2008)
S _{MK} box (SAM III) riboswitch (<i>Enterococcus faecalis</i>)	S-adenosyl-methionine	~ 850	4 helices, 1 coaxial stack, Y-shaped	3E5C	Lu <i>et al.</i> (2008)

capable of catalyzing through *in vitro* evolution experiments (Tables 1 and 2). This apparently limited use of ribozymes by contemporary organisms could reflect the intrinsic chemical

limitations of RNA as a catalyst, compared to proteins. On the other hand, key cellular processes (such as protein synthesis and tRNA maturation) are RNA-catalyzed. Thus, some

Figure 1 Cartoon representation of gene-regulation strategies employed by riboswitches. (a) Regulation at the transcription level. In the absence of ligand, the riboswitch forms an anti-terminator helix, which permits read-through by RNA polymerase. Upon binding the ligand, the riboswitch changes its secondary structure and forms instead a transcription terminator stem-loop. (b) The prematurely terminated RNA transcript from panel (a), in some cases, can also function as a noncoding RNA in *trans* and regulate translation initiation of a different mRNA. (c) The ribosomal binding site (RBS) is sequestered by the riboswitch in the presence of ligand. Sequestration of the RBS blocks translation initiation. (d) The *glmS* riboswitch-ribozyme is catalytically activated by ligand binding, cleaving the mRNA it is part of, resulting in a newly exposed 5'-OH. This is recognized by a ribonuclease, leading to degradation of the mRNA. (e) Regulation by splicing. In the absence of ligand, base-pairing between the α and α' elements (orange) brings the 5' and 3' splice sites close to each other favoring the principal splicing product. This base-pairing is disrupted when the riboswitch binds its ligand and sequesters the α' element, favoring splicing at alternative sites (AS) instead. The crystal structure of a riboswitch that exemplifies each of the five regulatory pathways is shown on the right.

properties of RNA must endow it with selective advantage over protein catalysts. Two possible such properties are that RNA is produced in one step from DNA (and thus ribozymes and riboswitches can be generated without the energetic cost or delay of protein synthesis), and that RNA, compared to protein, is much more mechanically stiff (thus allowing long-range communication within large macromolecular machines, such as the ribosome and the spliceosome).

Ribozymes in the Replication of Viroids and Virusoids

Ribozymes function in the replication of some viroids and virusoids. These are plant pathogens that consist solely of a single-stranded circular RNA, and are the smallest known replicating nucleic acids (only ~300 nucleotides). Unlike viruses, these pathogens lack protein coding capability, and are replicated by host RNA polymerases. Replication proceeds through a 'rolling-circle' mechanism (Figure 2(a)), in which the infectious RNA (the 'genomic RNA') is copied into concatenated RNAs of the opposite polarity (the 'antigenomic RNA'). This concatamer is cut into unit-length pieces, which then circularize to form antigenomic circles. Copying of these and processing into circles regenerates the infectious RNA. In many viroids and virusoids, ribozymes (such as the hairpin and hammerhead ribozymes) catalyze the cleavage and circularization reactions. A fungal parasitic DNA (the Varkud satellite of *Neurospora* mitochondria) employs a ribozyme in a related reaction. A human satellite virus of the Hepatitis B virus called the hepatitis δ virus (HDV) is strikingly similar to viroids (albeit somewhat larger), is copied by the human RNA polymerase II, and relies on self-cleaving ribozyme domains in both the genomic and antigenomic RNAs for processing. Remarkably, recent biochemical and bioinformatic experiments have shown that RNAs resembling the HDV ribozyme are scattered through phylogeny, from bacteriophage and bacteria through all animal phyla examined. The strong association of these HDV ribozyme-like RNAs with non-LTR retrotransposons suggests that the catalytic RNA serves an essential function in the physiology of this selfish genetic elements. The hammerhead ribozyme has also been found to be distributed across all of phylogeny, but its biological function is not well understood.

Ribozymes as Mobile Genetic Elements

Group II introns are self-splicing ribozymes present mostly in organellar pre-mRNAs. They catalyze two sequential steps (Figure 2(b)), and the transesterification reactions are reversible. The spliced intron sequence, interestingly, often includes an open reading frame encoding a large protein with reverse-transcriptase activity. This protein has been shown to associate with the ribozyme. The RNP thus formed is a mobile genetic element that can hop from its location in an intron-containing allele to the equivalent location in an intron-free allele, in a process of gene conversion. This is catalyzed both by the RNA and the protein component of the RNP. The spliced intron is responsible for locating the site of insertion into the intron-free allele, and cleaving one of the strands of the recipient DNA. The protein is responsible for the rest of the reaction in which the RNA is reverse-transcribed into the recipient. Although no

mobile group II introns have been detected in eukaryotic nuclear genomes, the mechanistic and structural similarity between these introns and the spliceosome suggests that pre-mRNA introns, together with the splicing machinery, might be remnants of ancestral group II intron-like mobile genetic elements.

The Ribosome as a Ribozyme and Riboswitch

In addition to being an RNA that catalyzes peptide bond formation, the ribosome is responsible for the process of decoding, that is, binding to tRNAs that are specified by the bound mRNA. Structural studies have demonstrated that the small subunit of the RNA carries out proof-reading of the match formed between the mRNA codons and the tRNA anticodons employing exclusively RNA. In this sense, the decoding site of the ribosome can be thought of as a programmable riboswitch. In order to function in protein synthesis, the ribosome must translocate to successive codons, and repeatedly form peptide bonds between the nascent polypeptide and the next amino acid, which is brought into the active site esterified to its cognate tRNA. Although, biologically, the process of translocation is catalyzed by proteins (elongation factors), studies using antibiotics have shown that the ribosome can translocate on its own (Konevega *et al.*, 2007). Such studies demonstrate that the ribosome can function solely on the basis of the free energy of peptide bond formation, and by co-opting the thermal energy of its surrounding solvent molecules.

The *glmS* Ribozyme–Riboswitch

The *glmS* riboswitch–ribozyme is another example of a riboswitch that is also a catalytic RNA. This ribozyme resides in the 5' UTR of the gene encoding glucosamine-6-phosphate (GlcN6P) synthetase (GlmS) in Gram-positive bacteria. Unlike other ribozymes that cleave RNA sequence-specifically, this RNA is inactive until it binds to GlcN6P. GlcN6P functions as a true coenzyme of the ribozyme, providing a key catalytic group to the otherwise preformed (but inert) ribozyme active site. In Gram-positive bacteria, intact mRNAs have a 5' triphosphate group. Self-cleavage by the *glmS* ribozyme–riboswitch domain exposes a 5'-OH group, and this is the signal that triggers degradation of the rest of the mRNA by the ribonuclease J1 protein (Collins *et al.*, 2007). Because the GlmS protein is unstable, destruction of its mRNA results in shutdown of GlcN6P production, thus completing negative feedback regulation mediated by this riboswitch–ribozyme. This RNA is of particular interest in evolutionary considerations because it is thus far the only known example of a natural RNA that employs a catalytic coenzyme. Analogously to the use of diverse coenzymes and prosthetic groups by protein enzymes, if RNAs can employ exogenous small molecules in their active sites, they could readily overcome limitations arising from the relatively simple chemical composition of nucleic acids. Indeed, it has been argued, based on the chemical similarity between many coenzymes and nucleic acids, that coenzyme utilization by modern protein enzymes is a remnant of an earlier metabolism where RNAs were responsible for forming the active sites of primordial proteins or peptide aggregates.

Figure 2 Examples of RNA processing mediated by ribozymes. (a) Rolling-circle replication employed by viroids and virusoids. Upon infection, the monomeric, circular viroid RNA ('genomic' sense, blue) is transcribed by a host RNA polymerase to generate a multimeric 'antigenomic' RNA (red). The antigenomic RNA is processed to unit-length copies by self-cleaving ribozyme domains (dotted arrow indicates cleavage site) and circularized by ligation. This process is repeated in the opposite direction to regenerate the genomic strand. (b) Splicing by Group II introns. This process involves two sequential steps: (1) nucleophilic attack of the 5' exon-intron junction, (2) nucleophilic attack of the 3' exon-intron junction. This results in the ligation of the two exons, and liberation of the intron as a lariat. Group II introns can alternatively employ water as a nucleophile in the first splicing reaction, yielding a linear intron and ligated exons (hydrolytic splicing). The crystal structure of a ribozyme involved in each of the two RNA processing pathways is shown on the right.

Ribozymes and Riboswitches as Cell Biological Tools

Ribozymes and riboswitches perform numerous gene regulatory tasks in modern cells. In addition, they have the potential to be employed as cell biological tools. Unlike tools such as anti-sense RNAs, siRNAs, and CRISPR, which rely on Watson–Crick base complementarity, riboswitches and ribozymes can function by directly recognizing the three-dimensional structures of their ligands, cofactors and substrates. Therefore, ribozymes and riboswitches have the potential to access a larger fraction of cellular molecules. For instance, ‘Spinach’ an aptamer RNA that binds to a latent fluorophore (a compound that does not become fluorescent until bound to the aptamer RNA) has been converted into a sensor for small molecule metabolites by fusing it to the ligand-binding domains of natural riboswitches (Paige *et al.*, 2012). Several artificial riboswitches that control gene expression in living cells in response to exogenous small molecules have been described (Sinha *et al.*, 2010). These overcome the difficulty in using natural riboswitches in recombinant contexts that arises from the fact that natural riboswitches are controlled by ubiquitous and essential cellular metabolites. Ribozymes that function as mobile genetic elements have the potential to be utilized for manipulating genomes *in vivo*. Molecular engineering efforts to harness the structural versatility of ribozymes and riboswitches represent a promising avenue of research.

Glossary

Elongation factors Proteins that promote the extension of the protein chain by the ribosome.

Initiation factors Proteins that help the ribosome to start the process of protein synthesis on an mRNA.

Messenger RNA RNA molecules that carry information to the ribosome for protein synthesis.

Ribosome Cellular structures made of RNA and protein molecules that synthesize proteins that the cells need for growth and division.

Termination factors Proteins that are required for the release of the newly synthesized protein from the ribosome and for the recycling of the ribosome.

Transfer RNA RNA molecules that bring amino acids to the ribosome for protein synthesis.

Introduction

Ribosomes synthesize proteins by translating the genetic information in messenger RNAs and are one of the few macromolecular complexes in the cell that are composed of both proteins and RNAs. The active role played by the ribosomal RNAs (rRNAs) in protein synthesis is evidence that the ribosomes are a relic of the primitive RNA world. This article will focus on the functional role of the rRNAs in bacterial protein synthesis. In bacteria, the 70S ribosome (2.3 MDa) consists of the 50S large ribosomal subunit and the 30S small ribosomal subunit. The 50S ribosomal subunit is composed of 23S rRNA (2900 nts), 5S rRNA (120 nts) and more than 30 ribosomal proteins and is responsible for catalyzing peptide bond formation. The 30S ribosomal subunit is composed of 16S rRNA (1500 nts) and about 20 ribosomal proteins and is responsible for decoding the mRNA sequence. Aminoacyl-tRNAs are the substrates for protein synthesis and each ribosomal subunit has three tRNA binding sites designated aminoacyl site (A site), peptidyl site (P site), and exit site (E site). During protein synthesis, tRNAs bind first to the A site, then to the P site and finally to the E site in a step-wise fashion. This iterative tRNA binding process is the basis for the elongation cycle of protein synthesis.

Overview of Protein Synthesis

Protein synthesis is an energy intensive process requiring about 10 translation factors in addition to aminoacyl-tRNAs and the ribosome. The process of protein synthesis can be divided into four stages: (1) initiation, (2) elongation, (3) termination, and (4) recycling (Figure 1). During the initiation stage of protein synthesis, the 30S ribosomal subunit binds the mRNA and the initiator tRNA (formyl-methionine-tRNA^{Met}) with the help of initiation factors 1, 2, and 3 (IF1, IF2, and IF3) (reviewed in Boelens and Gualerzi, 2002). The initiator tRNA binds to the P site in the 30S subunit and interacts with the start codon in the mRNA. Correct base pair formation between the anticodon of the initiator tRNA and the start codon promotes the association of the 50S subunit to the 30S subunit and the release of IF1,

IF2, and IF3 from the ribosome. The ribosome then begins the elongation cycle of protein synthesis by binding elongation factor Tu•GTP•aminoacyl tRNA (EF-Tu ternary complex) to the ribosomal A site. Proper Watson–Crick base pair formation between the anticodon of the tRNA and the mRNA codon in the A site triggers the accommodation of the tRNA into the 50S subunit and the release of EF-Tu•GDP from the ribosome (reviewed in Rodnina *et al.*, 2005). The peptidyl transferase center in the 50S subunit then catalyzes peptide bond formation resulting in the extension of the nascent peptide by one amino acid. Next, the deacylated tRNA in the P site and the peptidyl-tRNA in the A site are translocated to the E and P sites, respectively, by the activity of elongation factor G (EF-G) (reviewed in Shoji *et al.*, 2009). This process also brings the next mRNA codon into the A site for interaction with EF-Tu ternary complexes. This cycle continues until a stop codon is placed in the A site. The stop codon in the A site is recognized not by an EF-Tu ternary complex but by release factors 1 or 2 (RF1 recognizes UAA and UAG where as RF2 recognizes UAA and UGA). RF1 and RF2 promote the release of the newly synthesized protein from the peptidyl-tRNA in the P site (reviewed in Zhou *et al.*, 2012a). RF1 and RF2 are released from the ribosome by the activity of RF3•GTP, which in turn hydrolyze GTP to dissociate from the ribosome. The ribosome is now left with a deacylated tRNA in the P site and the mRNA. This ribosomal complex binds RRF and EF-G, which separates the ribosome into the 50S and 30S subunits and the mRNA and tRNA are released from the 30S subunit by the proof-reading activity of IF3 (reviewed in Petty *et al.*, 2008). The vacant 50S and 30S subunits are free to start the whole process of protein synthesis again on another mRNA.

Functional Role of 16S and 23S rRNAs During Initiation

Interactions with mRNA

As described above, the process of protein synthesis begins with the 30S subunit binding an mRNA. The mRNA binds in a

Figure 1 Overview of bacterial protein synthesis. During translation initiation the 30S subunit binds an mRNA and the initiator tRNA with the help of IF1, IF2, and IF3. The 30S initiation complex then binds the 50S subunit to form 70S ribosome. The 70S ribosome enters the elongation cycle by binding EF-Tu-GTP-aminoacyl tRNA complex to the A site and catalyzing peptide bond formation. This is followed by mRNA-tRNA translocation catalyzed by EF-G-GTP. In the termination stage, RF1/RF2 binds to the ribosome with a stop codon in the A site and catalyzes the release of the newly synthesized protein. RF3-GTP then triggers the release of RF/RF2 from the ribosome. The 70S ribosome is recycled into the 30S and 50S subunits by the combined activities of RRF and EF-G.

channel between the 'head' and the 'body' of the 30S subunit and about 30 nucleotides of the mRNA from position -18 to $+12$ are accommodated by the ribosome (Figure 2; Yusupova *et al.*, 2001). Most bacterial mRNAs have a purine-rich sequence 4–8 nucleotides upstream of the start codon called the Shine–Dalgarno (SD) sequence (Shine and Dalgarno, 1974). The SD sequence in the mRNA forms Watson–Crick base pairs with a complementary sequence, the anti-SD sequence, present at the 3' end of the 16S rRNA. The SD/anti-SD duplex is located in a cleft at the back of the 'head' and 'platform' domains of the 30S subunit and interacts with helices 23, 28, and 37 of 16S rRNA and ribosomal proteins S11 and S18 (Figure 2 (d); Yusupova *et al.*, 2001; Korostelev *et al.*, 2007). The mRNA (positions -4 to -1) then passes through a short tunnel between the head and the platform of the 30S subunit to the subunit interface side, where it interacts with the 690 loop, the 790 loop, the 925 region of helix 28, and helix 45 of 16S rRNA. The mRNA then undergoes a turn around position -1 and the P and A site codons (positions $+1$ to $+6$) are exposed on the interface surface for base pairing interactions with the anticodons of P site and A site tRNAs. Interestingly, the mRNA has a sharp kink between the P and A site codon to allow for the simultaneous binding of two tRNAs. This kink in the mRNA is caused by the phosphate of nucleotide 1401 of 16S rRNA blocking the path of the mRNA. Some of the 16S rRNA nucleotides that contact the P site codon are 790, 791, 926, and 1498. The A site codon interacts with the universally conserved bases G530, A1492, and A1493 of 16S rRNA and protein S12. The mRNA downstream to the A site codon (positions $+7$ to $+10$) passes through another tunnel formed by helix 34 at the top, helix 28 on the right, the 530 loop on the left, and the 5' terminus of 16S rRNA, which forms a hairpin loop at the bottom. Finally, the mRNA (positions $+11$ to $+15$) passes through a ring of proteins (S3, S4, and

S5) to emerge on the backside of the 30S subunit. Proteins S3, S4, and S5 facilitate the disruption of mRNA secondary structure during translation (Takyar *et al.*, 2005). Thus, several highly conserved nucleotides of 16S rRNA interact intimately with the mRNA as it traverses the 30S subunit. Chief among these interactions for translation initiation is the formation of the SD/anti-SD duplex. Masking of the SD sequence by secondary structure in the mRNA or by the binding of proteins reduces the efficiency of translation initiation (de Smit and Van Duin, 1990; Brunel *et al.*, 1995; Studer and Joseph, 2006). Indeed, cells regulate the expression of some genes at the post-transcriptional level by changing the availability of the SD sequence. Finally, it is not clear exactly when the SD/anti-SD duplex is disrupted during protein synthesis.

Interactions with Initiation Factors

IF1, IF2, and IF3 are essential translational factors that promote the recruitment of mRNA and initiator tRNA to the 30S subunit to form the 30S initiation complex (30SIC) (reviewed in Boelens and Gualerzi, 2002; Milón *et al.*, 2012). These factors also ensure that the initiator tRNA interacts with the correct start codon so that the appropriate mRNA reading frame is translated. The role of IF1 is not clear, it has been proposed to stimulate the activities of IF2 and IF3. IF1 binds to the 30S subunit near the A site such that it would preclude the binding of a tRNA to the A site (Figure 3(a); Carter *et al.*, 2001). IF1 interacts with the 530 loop (helix 18) and helix 44 of 16S rRNA and with ribosomal protein S12 (Figure 3(b)). IF1 interacts specifically with A1492 and A1493 of 16S rRNA, inducing these bases to flip out of helix 44. IF1 also induces conformational changes within the 30S subunit that may affect the ability the 30S subunit to bind to the 50S subunit.

Figure 2 Structure of the ribosome. (a) Ribosome with three tRNAs in the A, P, and E sites. The 30S subunit consists of 16S rRNA (yellow) and 20 proteins (cyan) and the 50S subunit consists of 5S rRNA (teal), 23S rRNA (white), and 30 proteins (light blue). A site tRNA (green), P site tRNA (purple), and E site tRNA (blue) bind between the 30S and 50S subunits (PDB ID: 2WDK and 2WDL). (b) The 50S subunit viewed from the intersubunit side. The peptidyl transferase center (PTC in red), L1 stalk, Central Protuberance (CP), L11 region and 5S rRNA are indicated (PDB ID: 2WDL). (c) The 30S subunit viewed from the intersubunit side. The A, P, and E site tRNAs are shown. The 'head,' 'platform,' 'body,' and 'shoulder' domains of the 30S subunit are indicated. Helix 44 is in red (PDB ID: 2WDK). (d) Interactions of mRNA with the 30S subunit. The Shine-Dalgarno sequence of the mRNA (orange) base pairs with the 3' end of 16S rRNA forming a helix (SD/ASD in red) and interacts with 16S rRNA (yellow) and proteins S2, S11, and S18 (all in cyan) (PDB ID: 2HGR).

IF2 selectively stabilizes the initiator tRNA in the P site of the 30S subunit (Milon *et al.*, 2010). IF2 is a GTP/GDP binding protein that has a 'chalice' shaped structure with a globular N-terminal domain that interacts with the 30S subunit, G domain that binds GTP and C-terminal region that is used to recognize the formylated α -amino group of the initiator tRNA (Figure 3(c); Roll-Mecak *et al.*, 2000). IF2 binds on the interface side of the 30S subunit with the N-terminal region

close to helices 5 and 14 of 16S rRNA, the G domain contacting the GTPase-associated center of the 50S subunit and the C-terminal region interacting with the 3'-end of the initiator tRNA (Allen *et al.*, 2005; Myasnikov *et al.*, 2005; Simonetti *et al.*, 2008). IF3 prevents the premature association of the 30SIC with the 50S subunit (Antoun *et al.*, 2006a,b). It also carries out a similar function during ribosome recycling by preventing the re-association of the 30S and 50S subunits. IF3

(b) Close-up of IF1 interacting with 16S rRNA and protein S12 (cyan). (c) Structure of IF2/eIF5B. The N- and C-terminal domains are indicated and the GTP analog, GDPNP, is indicated by the blue spheres (PDB ID: 1G7T). (d) Structure of IF3 N and C-terminal domains (PDB ID: 1TIF and 1TIG).

enhances the fidelity of translation initiation by destabilizing the interaction of an incorrectly bound near- or non-cognate tRNA in the P site of the 30SIC (Antoun *et al.*, 2006a; Elvekrog and Gonzalez, 2013). It has N- and C-terminal globular domains connected by a flexible linker (Figure 3(d)). IF3 binds on the subunit interface side of the platform domain of the 30S subunit. The C-terminal domain interacts with helices 23, 24, and 45 of 16S rRNA, whereas the N-terminal domain interacts with the E site (Dallas and Noller, 2001; McCutcheon *et al.*, 1999). The binding of IF3 to 30S subunit is proposed to disrupt key intersubunit bridges formed by the platform domain with helix 69 of 23S rRNA (Dallas and Noller, 2001;

McCutcheon *et al.*, 1999), which is consistent with its function as an anti-association factor.

Interactions with Initiator tRNA

The initiator tRNA binds directly to the 30S subunit P site, which is mainly composed of 16S rRNA (Noller *et al.*, 2005). The interaction of 16S rRNA bases G1338 and A1339 in the P site with the initiator tRNA is important for IF3-dependent discrimination of initiator tRNA from elongator tRNAs (Lancaster and Noller, 2005). Other 16S rRNA nucleotides that

contact the P-tRNA are A790, G926, G966, A1229, C1230, C1400, and U1498 (Yusupov *et al.*, 2001; Korostelev *et al.*, 2006; Selmer *et al.*, 2006). Mutations of these bases have only a modest effect on translation. Similarly, the interactions of ribosomal proteins S9 and S13 with the anticodon arm of the P-tRNA are also not essential for translation (Hoang *et al.*, 2004). These results suggest that the interactions in the 30S subunit P site are redundant and initiation will occur as long as the initiator tRNA can bind with reasonable affinity to the P site (Hoang *et al.*, 2004).

Subunit Association and rRNA

Once the initiator tRNA has been properly placed in the P site, the 30SIC undergoes a conformational change that results in the anticodon of the initiator tRNA forming base pairs with the start codon (La Teana *et al.*, 1996). This also triggers the release of IF1 and IF3 from the 30SIC, followed by the binding of the 50S subunit to the 30SIC to form the 70S initiation complex (Tsai *et al.*, 2012). The G domain of IF2 interacts with the GTPase-associated center of the 50S subunit resulting in GTP hydrolysis on IF2 and the release of IF2•GDP from the 70S ribosome (Tomsic *et al.*, 2000). At the end of the initiation stage the ribosome contains a correctly positioned mRNA with the start codon interacting with the anticodon of the initiator tRNA in the P site and a vacant A site.

There are about a dozen contact points between the 30S and 50S subunits called intersubunit bridges that hold the subunits together in the 70S ribosome (Gabashvili *et al.*, 2000; Yusupov *et al.*, 2001; Korostelev *et al.*, 2006; Selmer *et al.*, 2006). Most of these bridges are composed of 16S rRNA interacting directly with the 23S rRNA; however, some of the bridges involve contacts between the rRNAs and ribosomal proteins. In particular, helix 44 of 16S rRNA, which lies at the interface of the 30S subunit, makes a number of contacts with the 50S subunit and IF1-dependent changes to the structure of helix 44 may control the rates of subunit association and dissociation (Carter *et al.*, 2001). Finally, some of bridges that connect the 30S subunit head with the 50S subunit are dynamically altered as the ribosome undergoes conformational changes during the translational cycle (Gao *et al.*, 2003; Frank *et al.*, 2007; Frank and Gonzalez, 2010). These bridges may play a functional role by coordinating the large-scale conformational changes in the ribosome and by biasing the movement of tRNAs.

Functional Role of 16S and 23S RNAs During the Elongation Cycle

Interactions of EF-Tu-GTP-Aminoacyl tRNA with the Ribosomal RNA

During the elongation stage, aminoacyl-tRNAs bind as an EF-Tu•GTP ternary complex to the A site (Figure 4(a)). The ribosome selects the cognate EF-Tu ternary complex while rejecting non-cognate EF-Tu ternary complexes with an error frequency of about 10^{-3} . Universally conserved 16S rRNA bases G530, A1492, and A1493 located in the decoding center of the 30S subunit play a crucial role in achieving this high

level of accuracy during tRNA selection (Ogle *et al.*, 2001). Upon cognate tRNA binding to the A site, G530, A1492, and A1493 undergo conformational changes to interact with the minor groove of the codon-anticodon helix (Ogle *et al.*, 2001). The first codon-anticodon base pair interacts with A1493. The second codon-anticodon base pair interacts with G530 and A1492. Finally, the third codon-anticodon base pair interacts less stringently with G530, which allows for wobble base pairs at the third position of the codon. G530, A1492, and A1493 interact stably with the cognate codon-anticodon helix because they have the proper A-form helical geometry. In contrast, the binding of a non-cognate tRNA with mismatches in the codon-anticodon helix deviates from A-form helical geometry, which destabilizes the interactions of G530, A1492, and A1493. In addition, non-cognate tRNAs fail to trigger a conformational change of the 30S subunit called 'domain closure' resulting ultimately in the rejection of the non-cognate tRNA (Ogle *et al.*, 2002). Thus, differences in the structure of the cognate tRNA•ribosome complex versus non-cognate tRNA•ribosome complex are proposed to be the molecular basis for fidelity. However, an alternate proposal is that the decoding center clamps tightly around the codon-anticodon helix forcing the mismatched base pair to adopt the geometry of a normal Watson-Crick pair, which is energetically unfavorable resulting in the rejection of the non-cognate and near cognate tRNAs (Demeshkina *et al.*, 2012).

GTP Hydrolysis

Binding of a cognate EF-Tu ternary complex to the ribosome accelerates GTP hydrolysis on EF-Tu, whereas non-cognate EF-Tu ternary complexes fail to stimulate rapid GTP hydrolysis and are released from the ribosome (reviewed in Rodnina and Wintermeyer, 2001). Interaction of the G domain of EF-Tu with the GTPase-associated center of the 50S subunit is critical for activating GTP hydrolysis. The GTPase-associated center consists of the universally conserved sarcin-ricin loop (helix 95) of 23S rRNA, the L11 protein and proximal rRNA (helix 43), and the L7/L12 ribosomal proteins (Figure 4(b); Schmeing *et al.*, 2009). The phosphate of A2662 in the sarcin-ricin loop is proposed to properly position the catalytic histidine residue in EF-Tu to allow a water molecule to carry out GTP hydrolysis (Voorhees *et al.*, 2010). A similar mechanism may be used by other translational GTPases to catalyze GTP hydrolysis on the ribosome. However, more biochemical and structural studies are necessary to precisely understand the steps that lead to GTPase activation and GTP hydrolysis.

Peptide Bond Formation

After GTP hydrolysis, EF-Tu•GDP dissociates from the ribosome and the aminoacyl-tRNA is accommodated into the 50S subunit A site. Peptidyl transferase reaction occurs in a deep cleft in the interface side of the 50S subunit (Ban *et al.*, 2000; Nissen *et al.*, 2000). The 3' aminoacyl end of the A site tRNA is in close proximity to the 3'-end of the peptidyl-tRNA in the P site (Korostelev *et al.*, 2006; Selmer *et al.*, 2006). The universally conserved CCA nucleotides at the 3' end of both tRNAs interact with conserved nucleotides in 23S rRNA. These

Figure 4 Interactions of elongation factors with the ribosome. (a) Structure of EF-Tu ternary complex bound to the 70S ribosome. EF-Tu ternary complex consist of EF-Tu (red), aminoacyl tRNA (green), and GTP (not shown). Also indicated are the decoding center (DC), P site tRNA (purple) and E site tRNA (blue) (PDB ID: 2XQD and 2XQE). (b) Close-up of EF-Tu ternary complex interacting with mRNA (orange), 23S rRNA (H43, H69, and H95 in white color), 16S rRNA (h5, h15, h18, and h44 in yellow color) and proteins (S12 and S13 in cyan color). (c) Structure of EF-G bound to the 70S ribosome. EF-G (red) interacts with the L7/L12 stalk and with the decoding center (DC) in the post-translocation state (PDB ID: 2WRI and 2WRJ). Close-up of EF-G interacting with 23S rRNA (H43, H69, H89, and H95 in white color), 16S rRNA (h5, h15, h18, and h44 in yellow color) and proteins (S12 and S13 in cyan color). (d) EF-G has five domains (labeled I to V) and domain I binds GTP (the GTP analog GDPNP is indicated by the blue spheres).

include Watson–Crick base pairs by C74 and C75 of the P site tRNA with G2252 and G2251, respectively, of the 23S rRNA (Samaha et al., 1995). Similarly, C75 of the A site tRNA forms a Watson–Crick base pair with G2553 of the 23S rRNA (Kim

and Green, 1999). Interestingly, the peptidyl transferase active site of the ribosome is composed only of 23S rRNA indicating that peptide bond formation is catalyzed by RNA and not by protein (Ban et al., 2000). Consistent with the structural data,

earlier biochemical studies showed that 23S rRNA extracted from the ribosome and free of most ribosomal proteins is capable of catalyzing peptide bond formation (Noller *et al.*, 1992). Most of the catalytic enhancement comes from the ability of the ribosome to precisely position the peptidyl-tRNA and the aminoacyl tRNA for the reaction (Beringer and Rodnina, 2007; Sievers *et al.*, 2004). Peptide bond formation results in a deacylated tRNA in the P site and the peptidyl-tRNA with a new amino acid added in the A site. Now the ribosome can spontaneously undergo a ratchet-like motion caused by the 30S subunit moving in a counter-clockwise manner relative to the 50S subunit (Frank and Agrawal, 2000; Cornish *et al.*, 2008). The ratchet-like movement partly translocates the 3'-end of the P and A site tRNAs into E and P sites, respectively, in the 50S subunit (Valle *et al.*, 2003). This creates hybrid tRNA binding states designated P/E and A/P states (Moazed and Noller, 1989; Spiegel *et al.*, 2007). The deacylated tRNA in the P/E state interacts with the P site in the 30S subunit and with the E site in the 50S subunit. The peptidyl-tRNA in the A/P state interacts with the A site in the 30S subunit and with the P site in the 50S subunit. The ratchet-like motion of the ribosomal subunits and the hybrid state formation by the two tRNAs are important for the translocation step of protein synthesis.

Interactions of EF-G with the Ribosomal RNAs

Translocation of the mRNA and the two tRNAs in the ribosome is catalyzed by EF-G. EF-G is a GTP binding protein and it has five domains (I–V). At present, there is no structure of ribosome•EF-G complex in the pre-translocation state. However, structures of the ribosome•EF-G complex in intermediate (Ratje *et al.*, 2010; Tourigny *et al.*, 2013; Zhou *et al.*, 2013; Pulk and Cate, 2013; Ramrath *et al.*, 2013) and in post-translocation states are available (Gao *et al.*, 2009). EF-G binds at the intersubunit space with domain I of EF-G contacting L12 ribosomal protein (Figure 4(c)). Domain II interacts with nucleotides in helices 5 and 15 of 16S rRNA in the shoulder domain of the 30S subunit (Figure 4(d)). Domain III, which is the GTP binding domain, interacts with helix 5 of 16S rRNA and the sarcin-ricin loop (helix 95) of 23S rRNA. Domain IV interacts with helices 44 and 69 of the 16S and 23S rRNAs, respectively. Finally, domain V interacts with helices 43, 44, 89 and the sarcin-ricin loop of 23S rRNA. How the interactions of EF-G with the ribosome promote GTP hydrolysis and translocation is not fully understood. Studies indicate that EF-G•GTP binds to the ribosome and stabilizes both the ratcheted state of the ribosome and tRNAs in the P/E and A/P hybrid states (Frank and Agrawal, 2000; Cornish *et al.*, 2008; Valle *et al.*, 2003; Spiegel *et al.*, 2007; Agirrezabala *et al.*, 2008). Interaction of EF-G•GTP with the ratcheted ribosome triggers GTP hydrolysis, which accelerates translocation of the two tRNAs from the P/E and A/P hybrid states to E/E and P/P states (Rodnina *et al.*, 1997; Cunha *et al.*, 2013). Thus, EF-G mainly catalyzes the movement of the anticodon arms of the two tRNAs relative to the 30S subunit. The mRNA also moves by one codon towards the E site by virtue of forming base pairs with the anticodons of the P and A site tRNAs. During translocation, both EF-G and the ribosomes undergo dynamic

changes that may bias the directional movement of the tRNAs. For example, domain IV of EF-G moves deeper into the decoding center, the head domain of the 30S subunit undergoes a rotation relative to the body of the 30S subunit, L1 stalk moves closer to the P/E tRNA, and the L7/L12 stalk contacts EF-G are some of the conformational changes that occur during translocation (reviewed in Frank, 2012; Noeske and Cate, 2012; Korostelev *et al.*, 2008). Thus, translocation is one of most complex process orchestrated by the ribosome.

Interaction of Ribosomal RNAs with E-tRNA

Translocation is completed when the deacylated tRNA is in the E/E state and the peptidyl-tRNA is the P/P state. The 50S subunit E site has a higher affinity for deacylated tRNA than for aminoacylated tRNA partly explaining the spontaneous movement of the 3'-end of the P site tRNA into the E site after peptide bond formation. The 3' end of E site tRNA interacts with a deep pocket that is separate from the peptidyl transferase cleft and is composed of helices 11, 74, and 75 of 23S rRNA (Yusupov *et al.*, 2001; Korostelev *et al.*, 2006; Selmer *et al.*, 2006). The anticodon arm of E site tRNA is located between the head and platform domains of the 30S subunit and interacts with the 690 loop, 790 loop, helices 28, 29, and 42 of 16S rRNA. Additionally, ribosomal proteins S7, L1 and L33 contact the E site tRNA. The deacylated tRNA spontaneously dissociates from the E site of the post-translocation state ribosome. This resets the ribosome to the start of the elongation cycle with the ribosome having the peptidyl-tRNA in the P site and vacant E and A sites. It has been debated in the literature whether the anticodon of the E site tRNA remains base paired to the mRNA codon after translocation (Wilson and Nierhaus, 2006). This issue has not been settled with the current structural data because they contain incorrect codon–anticodon combinations that were formed presumably by deacylated tRNAs binding directly to the E site.

Functional Role of 16S and 23S RNAs During Termination

Interactions with Release Factors 1 and 2

The elongation cycle continues to add amino acids to the growing nascent polypeptide chain as dictated by the mRNA codons until a stop codon enters the A site. The nearly universal stop codons UAA, UAG, and UGA are recognized by class I release factors. In bacteria, two class I release factors (RF1 and RF2) recognize the stop codons with overlapping specificity. RF1 recognizes the stop codons UAA and UAG, while RF2 recognizes the stop codons UAA and UGA (Scolnick *et al.*, 1968). RF1/RF2 binds to the ribosome with a stop codon in the A site and catalyze hydrolysis of the ester bond linking the newly synthesized protein to the tRNA in the P site. RF1 and RF2 bind to the ribosomal A site and occupy the same space as the aminoacyl tRNA (Figure 5(a); Klaholz *et al.*, 2003; Rawat *et al.*, 2003; Petry *et al.*, 2005; Weixlbaumer *et al.*, 2008; Laurberg *et al.*, 2008). Residues important for stop codon recognition, including a tripeptide anticodon motif in domain

Figure 5 Interactions of release factors 1 and 3 with the ribosome. (a) Structure of RF1 bound to the 70S ribosome. Indicated are RF1 (red), P site tRNA (purple), E site tRNA (blue), the peptidyl transferase center (PTC) and the decoding center (DC) (PDB ID: 3D5A and 3D5B). (b) Close-up of RF1 interacting with 16S rRNA (h18 and h44 in yellow color), 23S rRNA (H69 and bases A2451, C2452, G2583, and A2602 of the PTC; all in white color) and proteins (S12 and S13 in cyan color). The GGQ and PxT motifs of RF1 are indicated. (c) Structure of RF3 bound to the 70S ribosome. RF3 (red) and tRNA in the P/E hybrid state (pink) are shown (PDB ID: 3ZVO and 3ZVP). (d) Close-up of RF3 interacting with 16S rRNA (h5 and h15 in yellow color), 23S rRNA (H43, H89, and H95 in white color), and proteins (S12 in cyan and L6 in light blue). The GTP analog, GDPCP bound to RF3 is indicated by the blue spheres.

II of RF1 and RF2 (PxT in RF1 and SPF in RF2) (Ito *et al.*, 2000) are located in the decoding center of the 30S subunit. In addition, all class I release factors have a GGQ motif in domain III, which is important for peptidyl-tRNA hydrolysis, is located in the peptidyl transferase center next to the 3' end of P site tRNA (Figure 5(b)). The two glycines in the GGQ motif are conserved to correctly position the glutamine in the active

site for peptide hydrolysis. The backbone amide of glutamine contributes directly to catalysis by transition state or product stabilization (Laurberg *et al.*, 2008; Youngman *et al.*, 2008). Interestingly, several of the conserved bases in 23S rRNA that form the peptidyl transferase center are essential for peptide release rather than for peptide bond formation (Youngman *et al.*, 2004). Thus, the peptide release reaction is very sensitive

to disruptions in the active center. This may be exploited by the ribosome to increase the fidelity of termination by coupling stop codon recognition by RF1/RF2 to the proper placement of the GGQ motif in the peptidyl transferase center (He and Green, 2010; Field *et al.*, 2010).

Interactions with Release Factor 3

After peptide release, RF1 and RF2 remain bound to the ribosome. The next step in termination is the removal of RF1 or RF2 from the ribosome by the action of RF3. RF3 is a member of the GTPase superfamily and consists of three domains. Domain I of RF3 binds GTP and is known as the G domain. The current model is that RF3•GDP binds to the release complex consisting of a deacylated tRNA in the P site and either RF1 or RF2 in the A site (Zavialov *et al.*, 2001). RF3 then exchanges GDP for GTP on the ribosome. The exchange reaction results in an increase in the affinity of RF3•GTP for the ribosome and promotes the dissociation of RF1/RF2. RF3 hydrolyzes GTP, switches to its low affinity GDP form, and leaves the ribosome. However, more recent studies indicate that RF3•GTP binds to the ribosome to trigger the release of RF1/RF2 from the ribosome (Peske *et al.*, 2013).

Structural studies showed that RF3 binds at the entry to the intersubunit cavity and its binding site overlaps with the binding sites for EF-Tu ternary complex and EF-G (Figure 5(c); Klaholz *et al.*, 2004; Jin *et al.*, 2011; Zhou *et al.*, 2012b). As expected, domain I of RF3 interacts with the sarcin-ricin loop (helix 95) of 23S rRNA and protein L6 (Figure 5(d)). A conserved histidine in domain I of RF3 that is important for GTP hydrolysis is located close to the sarcin-ricin

loop. Domains II and III interact with helices 5 and 15 of 16S rRNA and protein S12. The binding of RF3 to the ribosome induces the ratchet-like rotation of the subunits and the movement of the deacylated tRNA from P/P state to P/E state (Jin *et al.*, 2011; Sternberg *et al.*, 2009). Structural changes also occur in the GTPase-associated center (helices 42–44 of 23S rRNA) and in the decoding center (Jin *et al.*, 2011; Zhou *et al.*, 2012b). The ratcheted state of the ribosome induced by RF3 creates steric clash between the head domain of the 30S subunit and domain IV of RF1/RF2, and between the L11 stalk of the 50S subunit and domain I of RF1/RF2. These unfavorable interactions between RF1/RF2 and the ribosome are proposed trigger their release from the ribosome.

Functional Role of 16S and 23S RNAs During Recycling

Interactions with Ribosome Recycling Factor

In the final stage of protein synthesis the ribosomes with an mRNA and a tRNA in the P site are separated into 30S and 50S subunits by the activities of RRF and EF-G (Zavialov *et al.*, 2005; Peske *et al.*, 2005). RRF has two domains and forms an L-shaped structure, which mimics the overall shape of a tRNA (Selmer, 1999). However, RRF does not bind to the same sites as tRNAs on the ribosome. Instead, RRF binds in the subunit interface with domain I spanning the A and P sites of the 50S subunit and domain II is close to protein S12 of the 30S subunit (Figure 6(a); Lancaster *et al.*, 2002; Wilson *et al.*, 2004; Agrawal *et al.*, 2004; Weixlbaumer *et al.*, 2007;

Figure 6 Interactions of ribosome recycling factor with the ribosome. (a) Structure of RRF bound to the 70S ribosome. Indicated are RRF (red), mRNA (orange), P site anticodon stem-loop (P-ASL in purple), and E site tRNA (blue) (PDB ID: 2V46 and 2V48). (b) Close-up of RRF interacting with 16S rRNA (h44 in yellow color), 23S rRNA (H69, H71 and the P-loop; all in white color) and proteins (S12 in cyan, L16 and L27 in light blue).

Borovinskaya *et al.*, 2007). The tip of domain I contacts the P-loop of 23S rRNA (residues 2246–2258) and will clash with the acceptor arm of tRNA in the P/P state (Figure 6(b)). This suggests that the binding of RRF to the ribosome will favor the movement of the P-tRNA to the P/E hybrid state. Additionally, RRF may change the conformation of helix 69 of 23S rRNA, which forms important intersubunit bridges (Lancaster *et al.*, 2002; Wilson *et al.*, 2004; Agrawal *et al.*, 2004). There is no structure of RRF and EF-G bound simultaneously to the ribosome. Therefore, the exact mechanism for how RRF and EF-G trigger subunit dissociation is not known. It is possible that the binding of both RRF and EF-G to the ribosome may drive the P site tRNA to the P/E hybrid state and the ribosome to undergo the ratchet-like rotation, which ultimately disrupts the intersubunit bridges and cause the 30S and 50S subunits to separate (Gao *et al.*, 2005). IF3 then binds to the 30S subunit, preventing it from reassociating with the 50S subunit and also promoting the dissociation of the mRNA and tRNA from the 30S subunit (Zavialov *et al.*, 2005; Peske *et al.*, 2005). The 30S subunit•IF3 complex is free to initiate protein synthesis on a new mRNA.

Functional Role of 5S rRNA

The 5S rRNA is the smallest of the three rRNAs and is universally present in all organisms. Although 5S rRNA is essential for the activity of the ribosome, its functional role is still a mystery. The 5S rRNA is located in the central protuberance of the large ribosomal subunit and it interacts with 23S rRNA and ribosomal proteins L5, L16, L18, L25, L27, L30, L33, and L35 (Figure 2; Ban *et al.*, 2000; Selmer *et al.*, 2006; Korostelev *et al.*, 2006; Schuwirth *et al.*, 2005). The 5S rRNA and associated proteins contacts domain II (helices H38, H39) and domain V (H83–H85) of 23S rRNA, thus connecting these two structural domains of the 23S rRNA. This unique location for the 5S rRNA has led to the proposal that it may regulate the activities of these two functional centers of the ribosome (reviewed in Dinman, 2005; Gongadze, 2012). Additionally, since the central protuberance of the 50S subunit interacts with the head domain of the 30S subunit to form two intersubunit bridges (B1a and B1b) (Selmer *et al.*, 2006; Korostelev *et al.*, 2006; Schuwirth *et al.*, 2005), it is possible that the 5S rRNA-protein complex plays a role in subunit association. Finally, the head domain of the 30S subunit undergoes a rotation during mRNA–tRNA translocation (Zhang *et al.*, 2009), and the 5S rRNA-protein complex may coordinate this motion of the 30S subunit. More studies are needed to understand the precise function of this evolutionarily conserved RNA found in all three branches of life.

Glossary

AAA + protein AAA + stands for ATPases Associated with diverse cellular Activities. They contain a similar 'fold' of about 220 residues.

Clamp loader The clamp loader is a multiprotein assembly that uses ATP to assemble circular sliding clamps onto DNA. The clamp loader binds three substrates in this reaction, DNA, the sliding clamp, and ATP.

Distributive An enzyme is said to be distributive when it only performs one catalytic turnover for each substrate binding event.

DNA helicase DNA helicases are enzymes that couple ATP hydrolysis to separation of the strands of duplex DNA.

DNA polymerase DNA polymerases extend DNA by using dNTP substrates which they add to the 3' OH terminus of a preexisting RNA or DNA chain that is annealed to a template ssDNA strand. The DNA polymerase 'reads' the sequence of nucleotide bases in the template strand and matches complementary dNTPs to it.

LUCA This term is an abbreviation for 'last universal common ancestor' and is often thought of as a complete cell, from which all modern cells evolved. The nature of LUCA is highly disputed.

OB fold This is a common polypeptide fold within oligonucleotide and oligosaccharide binding proteins. These proteins typically bind single-strand DNA, RNA, or protein.

Okazaki fragment The term 'Okazaki fragment,' sometimes called 'lagging strand fragment' refers to the short segments of DNA that are synthesized discontinuously along the lagging strand. They are typically tipped at the 5' terminus with RNA, made by primase, and the RNA requires removal and replacement by DNA before Okazaki fragments can be joined together by the action of ligase.

Processive This term refers to the number of catalytic turnover events in one substrate binding event. For example, in polymerase action, the processivity of a polymerase is characterized by the number of dNTPs it incorporates into a DNA molecule before it dissociates from that molecule. In helicase action, this term refers to the number of base pairs that are melted (broken apart) in one helicase binding event on the DNA that it unwinds.

Proofreading exonuclease This is a 3'-5' exonuclease that is associated with the DNA polymerase, and 'proofreads' the product of nucleotide incorporation. If the polymerase makes a mistake, the new 3' terminus will not be correctly paired, and the 3'-5' exonuclease will remove the

mismatched 3' terminal nucleotide, enabling the DNA polymerase to try again.

Protein family These are proteins that are grouped together, most often due to having homologous sequences and therefore similar 3D structures. The similar sequence and structure is interpreted as having a common evolutionary ancestor with other proteins in the same family.

Protein fold This refers to the topological way that the polypeptide chain of a protein folds into a three-dimensional shape. A region within a protein that has the same 3D folding pattern as within another protein is referred to as having the same 'fold.'

RecA fold These are proteins that have a similar protein folding pattern as the RecA recombinase.

Replication Replication refers to the process of converting one DNA duplex into two new DNA duplexes.

Replication fork This is a commonly used term to indicate the point at which the two strands of parental DNA have been separated for duplication of the two daughter strands.

Replisome The term 'replisome' refers to the group of proteins that function together at a replication fork to convert one duplex into two new daughter duplexes.

Ribonucleotide reductase This is an enzyme that converts rNMPs into dNTPs, by removing the 2' hydroxyl group from the ribose, and replacing it with a proton. The fact that dNTPs are made from rNTPs, and are not synthesized de novo, is consistent with the RNA world hypothesis that invokes the presence of RNA before DNA.

RNA primase Primase is an enzyme that starts nucleic acid polymers with complementary sequence to a template single-strand, which it uses as a substrate. The primer oligonucleotides it creates are typically made of RNA and are short, 4–12 nucleotides.

Sliding clamp The sliding clamp is a term used to refer to the ring-shaped proteins that encircle DNA and slide freely along the duplex. Sliding clamps bind DNA polymerase, acting as a mobile tether to hold the polymerase to DNA for many rounds of dNTP incorporation.

Single-strand binding protein (SSB) SSB refers to a 'single-strand DNA-binding protein.' There are many types of SSBs. But when referred to in the context of DNA replication, SSB is reserved for the bacterial SSB homotetramer, required for replication. The eukaryotic and archaeal functional equivalent is referred to as replication protein A (RPA), a heterotrimer with distinct structure from bacterial SSB.

Introduction

The elegant double helical structure of deoxyribonucleic acid (DNA) belied the secret of just how difficult it would be to

replicate this simple structure. Watson and Crick recognized the need for considerable untwisting of the DNA strands for its duplication ([Watson and Crick, 1953a,b](#)), which we now know are resolved by topoisomerases, but they could not have

envisioned just how many proteins are actually required to perform the job of DNA replication. Here we provide an overview of the current state of knowledge about the proteins that function at replication forks in bacteria and eukaryotes.

The fact that the DNA strands are complementary led Watson and Crick to suggest that DNA may self-replicate without needing a protein, although they were open to the idea of an enzyme that ‘reads’ each strand to replicate DNA (Watson and Crick, 1953a). This issue was put to rest with the discovery of DNA polymerase (Pol) I by Arthur Kornberg (Lehman *et al.*, 1958). We now know that all cells contain multiple types of DNA Pols for replication and for DNA repair (Hubscher and Maga, 2011; Kornberg and Baker, 1992; Yang and Woodgate, 2007). However, there are many other, completely unanticipated proteins needed for replication in all cell types. Two of these are the circular sliding clamp, which tethers DNA polymerases to DNA, and the clamp loader machine that assembles these clamps onto DNA (Kelch *et al.*, 2012; O'Donnell and Kuriyan, 2006). Another is ribonucleic acid (RNA) primase, required to initiate DNA synthesis (Frick and Richardson, 2001; Kornberg and Baker, 1992). Replication also requires a DNA helicase to melt the parental duplex (Kornberg and Baker, 1992). Another essential protein, ubiquitous in all life forms, is a single-strand (ss) DNA binding protein that protects and organizes single-stranded DNA (ssDNA) produced as the helicase unwinds DNA (Kornberg and Baker, 1992). We came to understand that these proteins function in a coordinated manner, as gears within a ‘replisome’ machine (Alberts, 1984). And with time, learned that the proteins of the replisome are not fixed, but instead are highly dynamic and can interchange parts during replication (Langston *et al.*, 2009).

Comparisons of bacterial, eukaryotic, and archaeal genomes reveal that the sequences of the core translation and transcription machinery are conserved in all three domains of life. Given the conservation in these information processing systems it is surprising that the core replication enzymes of bacteria and eukaryotes/archaea are not conserved (Leipe *et al.*, 1999). Replication forks require the direct action of DNA polymerases, RNA primase, DNA helicase, and single-strand binding protein (SSB), yet these central proteins in bacteria and in eukaryotes share no common ancestor, while these same components in archaea are related to those in eukaryotes (Forterre, 2013; Leipe *et al.*, 1999). The implication is that the last universal common ancestor (LUCA) cell did not replicate DNA the same way as any modern cell, and may have had an RNA genome (Forterre *et al.*, 2004; Leipe *et al.*, 1999). Thus the DNA replication machinery developed later, after the branch point of bacteria and archaea/eukaryotes (Figure 1). Bacteria evolved one solution to replicate DNA while eukaryotes/archaea developed a different one.

The discovery of catalytic RNA (Kruger *et al.*, 1982) led to the RNA world hypothesis (Woese, 1968), which posits that the first enzymatic functions were performed by ribozymes, most of which were later replaced by proteins. The ribosome is a prime example of a ribozyme in all modern day cells. Sequence homologies reveal that the ribosomal RNAs, transfer RNAs (tRNAs), and aminoacyl tRNA synthetases in all domains of life share a common ancestor. All cells also use the same genetic code. These facts imply that protein synthesis was

Figure 1 Independent evolution of two DNA replication systems in bacteria and eukaryotes/archaea. (a) Common genes for transcription (RNA polymerase) and translation (rRNA, tRNAs, and amino acyl (aa) synthetases), and the same genetic code among all three domains of life indicate that LUCA had a fully formed transcription and translation apparatus. The universal homology of ribonucleotide reductase (RDR), ligase, and DNA dependent RNA polymerase indicate LUCA had DNA. However, the central enzymes of replication are nonhomologous between bacteria and the eukaryotic/archaeal domains of life, indicating that bacterial and eukaryotic replication enzymes evolved independently. (b) One hypothesis of information transfer in LUCA that included DNA (illustrated) is that LUCA had an RNA genome which was reverse transcribed into duplex DNA, as occurs in the life cycle of many modern RNA viruses. The DNA is then transcribed to form RNA for the genome and for translation.

highly developed in LUCA. In fact, the RNA polymerases of bacteria and eukaryotes are also homologous in all cell types, and they use DNA as a substrate. Ribonucleotide reductase, which converts NMPs to dNMPs is also conserved in all domains of life. These facts strongly suggest that LUCA had DNA, even if it did use RNA as the genome repository of information.

The finding that key replication enzymes of bacteria and eukaryotes are not homologous, yet LUCA had DNA, suggests that LUCA used another means of DNA synthesis (Leipe *et al.*, 1999). If LUCA had an RNA genome, why did it make DNA and how did it replicate? One proposal is that LUCA replicated in similar fashion to certain modern retroviruses that have RNA genomes, but use duplex DNA as a substrate for translation and replication. The RNA is reverse transcribed into DNA, then the RNA strand is digested by a nuclease followed

Table 1 Evolutionary relationship of replication fork proteins in bacteria and eukaryotes

Protein	Common ancestor	Fold pattern	Bacterial	Eukaryotic
Polymerase	No	C- vs B family	Pol C/Pol III	Pol α, δ, ϵ
Clamp	Yes	Same	β	PCNA
Clamp loader	Yes	Same	τ complex	RFC
Helicase	No	RecA vs AAA +	DnaB	Mcm2–7 (CMG)
Primase	No	Toprim vs Pol X	DnaG	Pri1
SSB	No	OB	SSB	RPA
Additional factors	No			Mcm10, Ctf4, GINS, and Cdc45

by conversion to duplex DNA (Figure 1). The DNA then serves as substrate for transcription by RNA polymerase to form transcripts and new copies of the RNA genome. It is interesting to note that this pathway does not require helicases, primase, clamps, and clamp loaders.

RNA is intrinsically less stable than DNA, and the enhanced stability likely led, over time, to the use of DNA as the genetic repository, and thus evolution of the replication machinery. These and other hypothesis have been proposed in the comparative genomics field to explain the non-homology of central replication enzymes in bacteria compared to eukaryotes/archaea (Forterre, 2013; Leipe *et al.*, 1999). Other possibilities exist, such as LUCA used DNA for its genome and had two replication systems, one being retained in bacteria and the other in eukaryotes/archaea. But this implies that replication in LUCA was much more complicated than in modern cells. One can consider whether the large size and nucleosome packaging of eukaryotic genomes selected for changes in replication strategy. But archaeal and eukaryotic replication proteins are homologous yet archaea, like bacteria, do not have nucleosomes or large genomes; they also generally have circular chromosomes without telomeres, and replicate rapidly like bacteria.

Regardless of how the different replication enzymes evolved, it is remarkable that the process is performed by proteins with the same biochemical function, even though the enzymes have distinct mechanisms and structures to perform these tasks (Table 1). Given the distinct evolutionary paths to replication, it is possible, even probable that the mechanics by which the proteins function together to accomplish replication will have significant differences. This review gives an overview of the structure and function of the central proteins at replication forks in bacteria and eukaryotes. We conclude with discussion of how these several enzymes coordinate their activities within replisome machines. Protein nomenclature used in this review utilizes that of *Escherichia coli* for bacteria, and of budding yeast (*Saccharomyces cerevisiae*) for eukaryotes. Where relevant, the names for human and archaeal proteins are given in parenthesis.

Bacterial Replicative DNA Polymerases Are Distinct from Those of Eukaryotes

Functional Overview of Bacterial (C Family) and Eukaryotic (B Family) Replicative DNA Polymerases

DNA polymerases do not start their own DNA chain; they can only extend from a preexisting primed template junction

(Kornberg and Baker, 1992). All DNA polymerases extend DNA unidirectionally, 3'-5', a natural consequence of dNTP substrates that are activated at the 5' position of the ribose and not the 3' position. There are a variety of different DNA polymerases with diverse sequences, and they have been as-sorted into classes of homologous sequences, referred to as families. The major DNA polymerase families are A, B, C, D, X, and Y (Steitz, 1999; Yang, 2014). Crystal structure analysis reveals that all DNA polymerases are shaped like a right hand, with palm, fingers, and thumb domains (see Figure 2(a)). The folding patterns of these domains are distinct among the different families, consistent with their nonhomologous sequences.

The replicative polymerase of all bacterial cells (i.e., Pol III/C) is in the C family. *Escherichia coli* Pol III 'core' contains three subunits, the α subunit polymerase, the ϵ subunit proof-reading 3'-5' exonuclease, and the θ subunit of unknown function. Most bacteria lack θ , and many bacterial C-family polymerases contain a 3'-5' exonuclease within the same polypeptide chain instead of a separate protein (Barros *et al.*, 2013; McHenry, 2011). Some bacteria also contain a second C-family polymerase, thought to be involved in repair or an ancillary role in replication (McHenry, 2011).

Eukaryotes require three different DNA polymerases for chromosome replication, each in the B family (Garg and Burgers, 2005a; Johansson and Macneill, 2010; Stillman, 2008). The leading strand is performed by Pol ϵ (Kunkel and Burgers, 2008), the lagging strand is performed by Pol δ (Pursell *et al.*, 2007) and also by Pol α , which makes RNA/DNA primers (Conaway and Lehman, 1982). Each of these polymerases consists of multiple subunits. The second largest subunit is referred to as the B-subunit; the B-subunits of all three replicative polymerases share homology (Johansson and Macneill, 2010). The functions of the B-subunits are largely unknown. Each replicative polymerase has additional accessory subunits as well. The polymerase subunit of each replicative enzyme has recently been found to contain a zinc finger and an iron-sulfur (FeS) cluster (Netz *et al.*, 2011). The zinc finger is necessary to bind the B-subunit and the function of the FeS cluster is still under investigation (Sanchez Garcia *et al.*, 2004). Archaeal cells also utilize two distinct polymerases for leading (Pol B) and lagging (Pol D) synthesis and have a primase related to the primase of eukaryotic Pol α (discussed later) (Beattie and Bell, 2011; Ishino *et al.*, 2013).

The leading strand Pol ϵ consists of Pol2 (polymerase/exonuclease, p261 in human), the B-subunit/Dpb2 (p59 in human), and the small accessory subunits Dpb3 (p17 in

Figure 2 Distinct structure and organization of bacterial and eukaryotic DNA polymerases. (a) DNA polymerases have a right hand shape. Left: Cartoon illustration of T7 DNA polymerase with fingers (orange), palm (green), thumb (yellow) domains; the 3'-5' exonuclease domain is in gray. Reprinted from Beard, W.A., Wilson, S.H., 2003. Structural insights into the origins of DNA polymerase fidelity. Structure 11, 489–496, Copyright (2003) with permission from Elsevier. Right: Schematic of a right hand with anatomical features that are colored similar to the polymerase domains that carry the same name. (b) Organization of domains of polymerases in different families. Domains with similar structure and function are in full colors (e.g., palm of C and X families, palm of A, B, and Y families). Domains with similar function but different structure are outline colored (i.e., thumb and fingers). Domains of unrelated or unclear function are black and white. (c) Chain folding topology diagrams of palm domains in the eukaryotic B family and the bacterial C family. The conserved acidic residues that coordinate metal ions for catalysis are shown as three black dots. OB, OB fold; HTH, helix-turn-helix; pad, polymerase associated domain, also called 'wrist' or 'little finger'; PHP, polymerase and histidinol phosphatase. human) and Dpb4 (p12 in human) (Pursell and Kunkel, 2008). Dpb3 and Dpb4 are dispensable for viability in budding yeast, but Dpb2 is essential. Pol δ contains the Pol3 subunit (polymerase/exonuclease; p125 in human), the

B-subunit Pol31 (p50 in human), and accessory subunit Pol32 (p66 in human) (Garg and Burgers, 2005a; Stillman, 2008). Pol32 is not essential and Pol δ from higher eukaryotes contains a nonessential fourth subunit (p12 in human). Pol α is a

four-subunit complex consisting of Pol I (polymerase, p180 in human), the B-subunit Pol II (unknown function, p70 in human), Pri I (primase, p48 in human, Pri S in archaea), and Pri II (p58 in human, Pri L in archaea), which modulates primase activity (Garg and Burgers, 2005a; Johansson and Macneill, 2010; Stillman, 2008). All four subunits of Pol α are essential to viability in all cells examined thus far.

Crystal Structure of B- and C-Family DNA Polymerases

The first structure of a DNA polymerase was *E. coli* Pol I, a member of the A family that is mostly involved in repair (Pursell and Kunkel, 2008). Since that time, representative polymerases in all families have been crystallized, and all have been found to contain the same 'right hand' shape, with three major domains: a palm, fingers, and thumb (Figure 2(a); Johansson and Macneill, 2010; Steitz, 1999). The different polymerase families result in many variations in the structural architecture of these domains, but their folding into the right hand shape is universal. The three acidic residues that bind the two metal ions for catalysis are always found in the palm domain, and the dNTP binding site is located in the fingers domain (Beese and Steitz, 1991; Steitz, 2006). The thumb domain facilitates binding duplex DNA. Many DNA polymerases incorporate multiple dNTPs in one DNA binding event by sliding along DNA after successive dNTP additions. Binding of nucleotide induces a conformational change in the fingers domain that pairs the dNTP to the template strand, and checks for base pair accuracy by a conformational-induced fit mechanism in which only base pairs of the correct geometry trigger the catalytic step (Doublié *et al.*, 1999; Johnson *et al.*, 2003; Joyce *et al.*, 2008; Li *et al.*, 1998; Luo *et al.*, 2007; Santoso *et al.*, 2010). There are often one or more additional domains in DNA polymerases. An example of this is illustrated in Figure 2(a), for the 3'-5' proofreading exonuclease domain in T7 DNA polymerase. The alignment of the polymerase sequences, and the locations of the domains from their respective structures are shown in Figure 2(b).

The C-family polymerase of both *E. coli* and *Thermus aquaticus* contain the palm, thumb, fingers domains, and also a polymerase and histidinol phosphatase domain (PHP domain), a C-terminal domain, and a domain that binds a sliding clamp (see Figure 2(b); Bailey *et al.*, 2006; Lamers *et al.*, 2006; Lamers and O'Donnell, 2008; Wing *et al.*, 2008). Some PHP domains of C-family polymerases are metal-dependent nucleases and may play a role in proofreading (Barros *et al.*, 2013; Stano *et al.*, 2006). But in many C-family polymerases the PHP domain has lost ability to bind metal and appears inactive (Barros *et al.*, 2013; Lamers *et al.*, 2006). In these cases the replicative C-family polymerase either contains a separate 3'-5' exonuclease domain, or recruits a separate 3'-5' exonuclease subunit for proofreading, as with *E. coli* Pol III which recruits ϵ for proofreading (compare Pol C and Pol III in Figure 2(b)).

The first crystal structure of a B-family polymerase was RB69 bacteriophage gp43, homologous to eukaryotic replicative polymerases α , δ , and ϵ (Stano *et al.*, 2006). Like eukaryotic Pols δ and ϵ , RB69 Pol contains a proofreading 3'-5' exonuclease. The structures of the fingers and thumb domains

of different families are distinct (Figure 2(b)), but the palm domains that contain the 'active site' acidic residues in A-, B-, and Y-family polymerases are similar (the Y family are error-prone polymerases discussed later). The C-family palm fold, and location of the active site acidic residues, is distinct from the A, B, C families, but has similarity to the palm of X-family polymerases (Bailey *et al.*, 2006; Lamers *et al.*, 2006; Lamers and O'Donnell, 2008; Wing *et al.*, 2008). The chain folding topology of the palms of B and C families are shown illustrated in Figure 2(c). The significant sequence and structural differences between bacterial and eukaryotic polymerases underscore their distinctive evolutionary lineage.

Sliding Clamps Are Conserved in All Cell Types

Unlike the DNA polymerases (and primase, helicase, and SSB), bacterial and eukaryotic sliding clamps evolved from a common ancestor (Leipe *et al.*, 1999). Sliding clamps are ring-shaped proteins that encircle duplex DNA and freely slide along it (Gulbis *et al.*, 1996; Kong *et al.*, 1992; Krishna *et al.*, 1994; Moarefi *et al.*, 2000). One function of sliding clamps is to bind directly to replicative polymerases and tether them to DNA, endowing them with high processivity (Stukenberg *et al.*, 1991). Originally discovered in *E. coli*, bacterial clamps are a ring-shaped homodimer called β (Figure 3(a); Kong *et al.*, 1992; Stukenberg *et al.*, 1991). The β dimer has a 6-fold appearance that derives from three globular domains in each subunit; the three domains share the same chain fold. The outside of the ring is a continuous layer of antiparallel sheet that also forms the dimer interface. The inside of the ring is lined by helices that form a cavity with a diameter of about 35 angstroms; the width of β is equal to the length of one turn of B-form duplex DNA. The eukaryotic and archaeal clamps, proliferating cell nuclear antigen (PCNA), are also ring shaped and have the same chain folding pattern as bacterial β (Gulbis *et al.*, 1996; Krishna *et al.*, 1994). PCNA is a trimer and each monomer consists of two globular domains, giving the ring the same 6-fold appearance as *E. coli* β . The outer surfaces of both clamps carry a net negative charge, while the insides of the rings are positively charged.

The similar structures of β and PCNA reveal that they evolved from a common ancestor, but their amino acid sequences have diverged significantly. Rapid sequence divergence is common for proteins that serve structural functions, as they are not constrained by the precise geometries of active site residues needed at a catalytic center. Indeed, advanced sequence comparison algorithms are required to identify the common origin of the domains within clamp subunits, and the homology between β and PCNA (Leipe *et al.*, 1999).

The bacterial and eukaryotic clamps interact with numerous proteins, not just their respective replicative polymerases (Maga and Hubscher, 2003). The interaction of clamps with partner proteins is mediated by a peptide motif that binds a hydrophobic pocket on the surface of the clamp (Dalrymple *et al.*, 2001; Gulbis *et al.*, 1996). PCNA and β interact with proteins of repair, cell cycle regulatory proteins, DNA ligase, and specialized DNA polymerases involved in traversing DNA

Figure 3 Sliding clamps are conserved in all three domains of life. Ribbon (top) and space filling (bottom) representations of: (a) *E. coli* b (2POL), (b) yeast PCNA (1PLQ), and (c) *Pyrococcus furiosus* (1GE8).

lesions (De Biasio and Blanco, 2013; Maga and Hubscher, 2003).

The Clamp Loader Was Also Present in LUCA

Clamps do not get onto DNA by themselves, they require a multiprotein clamp loader that uses adenosine triphosphate (ATP) to open and close the clamps around DNA (Ellison and Stillman, 1998; Fien and Stillman, 1992; Jeruzalmi *et al.*, 2001; Stukenberg *et al.*, 1991). Clamp loaders, both bacterial and eukaryotic are composed of five subunits essential to clamp loading activity (Bowman *et al.*, 2004; Cullmann *et al.*, 1995; Jeruzalmi *et al.*, 2001). Clamp loader subunits also share sequence homology to one another and are members of one gene family (Cullmann *et al.*, 1995). Moreover, the sequences of clamp loading subunits of bacteria are clearly homologous to the clamp loading subunits of eukaryotes (Bunz *et al.*, 1993; Cullmann *et al.*, 1995; O'Donnell *et al.*, 1993), indicating that LUCA contained the clamp loader.

Overview of Clamp Loader Mechanism

The mechanism of the clamp loader has emerged from several key clamp loading crystal structures and biochemical studies (Ason *et al.*, 2003; Bowman *et al.*, 2004; Jeruzalmi *et al.*, 2001; Kelch *et al.*, 2011; O'Donnell and Kuriyan, 2006; Turner *et al.*, 1999). In overview, the clamp loader associates with the clamp

upon binding to ATP and opens the clamp at one interface (Dionne *et al.*, 2008; Kelch *et al.*, 2011; Paschall *et al.*, 2011; Zhuang *et al.*, 2006). The clamp loader has a notch in one side through which DNA can enter a central chamber, positioning the DNA through the clamp as illustrated in Figure 4(a) (Kelch *et al.*, 2011). The central DNA binding chamber is capped by a 'collar' composed of the C-terminal domains that have no opening for DNA to go through. Hence, only DNA with a flexible hinge can fit into the central chamber, because the DNA must make a sharp bend to exit the notch in the side of the chamber. This requisite flexibility is provided by the ssDNA portion of a primed template (Bowman *et al.*, 2005; Kelch *et al.*, 2011; Simonetta *et al.*, 2009). Once on primed DNA, the ATP sites are brought into register to hydrolyze ATP, thus ejecting the clamp loader and allowing the clamp to close around DNA.

The function of the clamp loader was initially identified in the *E. coli* system, referred to as γ complex (Stukenberg *et al.*, 1991). Each subunit contains a sequence motif of the AAA+ family (ATPases Associated with a variety of cellular Activities) (Cullmann *et al.*, 1995; Jeruzalmi *et al.*, 2002; Kelch *et al.*, 2012). The AAA+ family is huge and as its name implies, its members function in a wide range of biological actions that include vesicle fusion, protease, helicase, and origin initiation (Erzberger and Berger, 2006; Neuwald *et al.*, 1999). Like the clamp loader subunits, most AAA+ proteins are multiprotein complexes. The first AAA+ protein to be solved structurally was the δ subunit of the *E. coli* clamp loader (Guenther *et al.*, 1997). This C-shaped subunit revealed features of AAA+ proteins that

Figure 4 Clamp loaders spanning bacteria to eukaryotes have similar structure and function. (a) Overview of clamp loader mechanism. First diagram: The clamp loader has a central chamber accessible to DNA by a notch in the side. The clamp loader cannot bind the clamp when in the ADP bound form. Second diagram: ATP enables the clamp loader to bind and open the clamp. Third diagram: Primed DNA binds the clamp-clamp loader complex by passing through the opened ring and the notch in the side of the clamp loader. Fourth diagram: ATP hydrolysis is triggered and the clamp loader ejects, leaving the clamp to close around the primed site. Fifth diagram: DNA polymerase binds the clamp for processive DNA synthesis. (b) Illustration of the domain architecture of clamp loaders. Clamp loaders are circular pentamers, and each subunit has at least three domains. The N-terminal domains I and II are the AAA + ATPase region and domain III forms a tight circular collar. The five subunits are denoted, counterclockwise, A–E. A gap exists between AAA + domains of subunits A and E. The common names of each subunit are indicated for each clamp loader. The A subunit of the eukaryotic and T4 clamp loaders contain an extra C-terminal region that reaches across the notch to the E subunit (this domain is labeled A'). From Kelch, B.A., Makino, D. L., O'Donnell, M., Kuriyan, J., 2011. How a DNA polymerase clamp loader opens a sliding clamp. *Science* 334, 1675–1680. Reprinted with permission from AAAS. (c) Ribbon representations of clamp loaders. Each subunit is a different color. The clamp, when present, is gray. The DNA in the T4 bacteriophage clamp-clamp loader structure is yellow. Reproduced from Kelch, B.A., Makino, D.L., O'Donnell, M., Kuriyan, J., 2012. Clamp loader ATPases and the evolution of DNA replication machinery. *BMC Biology* 10 (34), with permission from BioMed Central.

have been proven to generalize to all crystal structures of AAA+ proteins. The AAA+ region folds into two domains, one domain contains the walker A and B sites that bind the nucleotide and the other domain forms a helical 'lid' that contains residues that interact with the nucleotide and may be used to regulate hydrolysis. Two key residues of the lid domain are basic residues referred to as sensor 1 and sensor 2 that sense ATP binding and modulate intersubunit communication (Guenther *et al.*, 1997). Different AAA+ proteins that serve various cellular functions contain additional domains at the N- and/or C-terminus of the AAA+ region. In the case of clamp loaders, all the subunits contain a C-terminal domain that forms a tightly associated 'collar' from which the AAA+ domains are suspended (Bowman *et al.*, 2004; Jeruzalmi *et al.*, 2001; Kelch *et al.*, 2011; O'Donnell and Kuriyan, 2006).

Structure Analysis of Clamp Loaders

Crystal structure analysis of the *E. coli* clamp loader reveals a circular arrangement of the five subunits, one δ , three γ , and one δ' , referred to as subunits A–E as illustrated in the leftmost diagrams of Figures 4(b) and 4(c). The notch in the side of the clamp loader is formed by a gap between the AAA+ domains of δ and δ' (Figure 4(b); Jeruzalmi *et al.*, 2001). The AAA+ domains form a shallow spiral. Only the γ subunits contain ATP sites, as δ and δ' lack a functional Walker A motif (i.e., P loop). The three ATP sites are located at the γ – δ' and the two γ – γ interfaces (Jeruzalmi *et al.*, 2001). The δ' subunit contributes a catalytic arginine finger residue to ATP bound in γ , and this bi-partite ATP site construction holds true for the other two ATP sites as well. The location of ATP sites at subunit interfaces is a general feature of AAA+ oligomers and enables communication and coordination among subunits during ATP hydrolysis. The structure of the eukaryotic clamp loader, replication factor C (RFC) in complex with the PCNA clamp (middle diagrams in Figures 4(b) and 4(c)) shows a similar circular arrangement of the five AAA+ subunits (each are distinct polypeptides), with the PCNA clamp located under surface generated by the AAA+ domains (Bowman *et al.*, 2004). RFC contains four ATP sites, but only three, at the positions analogous to those of γ complex, are required for clamp loading. One subunit of RFC, RFC1 (a subunit), contains additional N- and C-terminal extensions that are not present in bacterial clamp loaders. The additional RFC1 N-terminal region is not essential to clamp loading, or to cell viability (Gomes *et al.*, 2000; Majka and Burgers, 2004). But the additional C-terminal region of RFC1 (not present in the structure of Figures 4(b) and 4(c)) reaches across the notch between the A and E subunits and EM studies reveal that it binds to PCNA (Miyata *et al.*, 2005).

The bacterial γ complex and eukaryotic RFC contain a central chamber with dimensions consistent with binding duplex DNA, confirmed in a cocrystal of *E. coli* γ complex with a primed DNA substrate (Simonetta *et al.*, 2009). Interestingly, DNA acts as a scaffold to bring the subunits into a spiral with a pitch similar to A-form duplex DNA. The main protein connections to the duplex are formed by a loop in the AAA+ domains of each subunit that interacts only with the phosphodiester backbone of the template strand. Template ssDNA bends out the notch

between δ and δ' (Simonetta *et al.*, 2009). Significant advances in our knowledge of the clamp loader mechanism derive from structural studies of the T4 bacteriophage clamp loader, composed of four gp44 subunits and one gp61 protein, in complex with the gp45 clamp, primed DNA, and an ATP analog (Kelch *et al.*, 2011). Archaeal clamp loaders are also often constructed from four identical subunits and one additional subunit (Dionne *et al.*, 2008; Seybert *et al.*, 2002). These studies confirmed that the clamp loader binds the entire surface of the clamp in the active complex, and open the clamp by bending it into a right hand open spiral with DNA positioned through the open clamp (Figure 4(c)). Structures of different nucleotide-bound forms of the T4 clamp-clamp loader-primed DNA complex indicate that ATP hydrolysis proceeds stepwise, from one ATP site to the next, counterclockwise around the ring (i.e., from ATP bound to subunit B to C to D).

Why were clamps and the clamp loaders in LUCA, while other replicative machinery was not? If LUCA used an RNA genome and reverse transcriptase, as suggested in Figure 1, a simple presumption is that clamps were used to help reverse transcriptase stay on the nucleic acid, much as clamps are used by DNA polymerases in modern day cells.

Bacterial and Eukaryotic Replicative Helicases

Proposed Strand Exclusion Mechanism of Bacterial and Eukaryotic Replicative Helicases

DNA replication requires a helicase that harnesses the energy of ATP hydrolysis to separate the strands of DNA. Replicative helicases are circular hexamers that encircle one single strand and use ATP to motor along it, excluding the other strand (Ahnert and Patel, 1997; Hacker and Johnson, 1997; Lee *et al.*, 2014). The excluded single strand is thus prevented from annealing to the strand inside the helicase ring. Helicases generally operate with other proteins that keep the strands separated during unwinding, otherwise the two strands could simply reanneal in back of the helicase (von Hippel and Delagoutte, 2001). Single-strand DNA binding protein, discussed later, is one such protein. DNA polymerase also prevents strand reannealing by converting one unwound strand into a duplex. Helicases may also 'back slide,' allowing strands to reanneal, and a polymerase and/or single-strand DNA-binding protein may prevent backsliding and increase helicase efficiency (Donmez and Patel, 2008).

Numerous helicases exist for various functions, and based on sequence analysis are assorted into six superfamilies (SF1–SF6) (Singleton *et al.*, 2007). All but the SF1 and SF2 families are hexamers (Donmez and Patel, 2006; Enemark and Joshua-Tor, 2008). The ATP motor domains of the bacterial replicative helicase, exemplified by *E. coli* DnaB, are constructed from the RecA fold and are members of the SF4 superfamily. The eukaryotic/archaeal Mcm helicase is in the SF6 family based on the AAA+ fold. Bacterial DnaB and eukaryotic Mcm helicases travel in opposite directions (Bochman *et al.*, 2008; Bochman and Schwacha, 2008; LeBowitz and McMacken, 1986). Thus at a replication fork the prokaryotic helicase encircles the lagging strand while the eukaryotic/archaeal helicase surrounds the leading strand. Given the nonhomologous sequences, distinct

RecA versus AAA+ folds, and opposite directions of unwinding, the bacterial and eukaryotic/archaeal helicases are thought to have evolved independently (Leipe *et al.*, 1999).

Helicases use the energy of ATP hydrolysis to translocate along ssDNA, but it is not yet certain that the energy of ATP hydrolysis is coupled to DNA unwinding. Thermal breathing of DNA may occur with sufficient speed for unwinding (Johnson *et al.*, 2007). Specifically, ATP-driven helicase translocation along ssDNA and consequent occupation of thermally unwound DNA may be sufficient to explain helicase unwinding (Jeong *et al.*, 2004; Johnson *et al.*, 2007; Jose *et al.*, 2012). Helicases use one ATP every 1–2 bp unwound, and given the –12 kcal per ATP hydrolyzed and –3.6 kcal for 2 bp of duplex DNA, the energetics is consistent with either scenario (Delagoutte and von Hippel, 2001; Donmez and Patel, 2008; von Hippel and Delagoutte, 2001).

Bacterial Helicase Structure

E. coli DnaB helicase and the helicases of bacteriophage T4 and T7 are based on the RecA fold and the hexameric rings have the appearance of two tiers of rings, because the protein has N- and C-terminal globular regions (Bailey *et al.*, 2007; Wang *et al.*, 2008). The RecA-based domains form the C-terminal tier and act as the motor, while the N-terminal domains form a ring-shaped tier that acts as a collar. Both ring-shaped tiers have holes in their center that can accommodate DNA. Crystal structures of DnaB-ssDNA and the T7 gp4 helicase have been solved (Itsathitphaisarn *et al.*, 2012; Sawaya *et al.*, 1999; Singleton *et al.*, 2000; Toth *et al.*, 2003). The RecA motor domains form an asymmetric out-of-plane spiral arrangement of the domains due to different nucleotide-bound states within distinct subunits. The DnaB-ssDNA structure bound to ssDNA suggests the following mechanism of action, illustrated in Figure 5. Firstly, the binding of ssDNA to the DnaB hexamer molds the RecA tier of DnaB into a right hand spiral having the pitch of A-form DNA. Each subunit binds the phosphodiester bonds of two nucleotides, for a total of 12 nucleotides bound per hexamer. ATP is hydrolyzed in an ordered fashion around the hexamer, one ATP at a time. The subunit at the bottom of the 'spiral staircase' hydrolyzes ATP and the DNA interaction is broken. This subunit then traverses 12 nucleotides to the top of the staircase and rebinds ssDNA and ATP. As this process repeats itself, the staircase moves hand-over-hand along the ssDNA, two nucleotides for each ATP hydrolyzed.

Eukaryotic Helicase Structure

The eukaryotic Mcm2–7 helicase is composed of six unique subunits that form a ring, but Mcm2–7 is nearly inactive and it associates with five other proteins, Cdc45 and the four subunit GINS complex (Ilves *et al.*, 2010; Moyer *et al.*, 2006). Little is known about the function of Cdc45 and GINS (none contain ATP sites). The four GINS subunits are related by sequence and structure, but are distinct and are known to bind other replication proteins (Pol ϵ and Ctf4), hinting that the GINS may act as a scaffold. Thus the eukaryotic helicase is referred to as CMG (Cdc45, Mcm2–7, and GINS). CryoEM studies of CMG reveal that the Cdc45 and GINS subunits form an additional 'hole'

Figure 5 Hexameric helicase mechanism. (a) Hexameric helicases encircle one strand of DNA and exclude the other. ATP hydrolysis is used to propel the helicase along the strand it encircles, driving it into the forked junction. Although bacterial and eukaryotic helicases are constructed from nonhomologous chain folds and sequence they are both circular hexamers and operate by this strand exclusion mechanism. Both types of helicases have a double-ring appearance, the C-terminal domains form a 'tier' that faces the duplex and contains the ATP sites; the unwound DNA product extrudes from the domains that comprise the N-terminal 'tier.' Bacterial and eukaryotic helicases travel opposite directions, and thus encircle either the lagging or leading strands, respectively. (b) Schematic of proposed mechanism of hexameric helicases. The C-terminal domains form an A-form spiral 'staircase' upon binding ssDNA (left). Hydrolysis of ATP in the subunit at the bottom leads to dissociation of that domain from DNA, followed by relocation to the top of the staircase and rebinding to ATP and ssDNA (middle), moving the helicase either one (eukaryotic) or two (bacterial) nucleotides. The right diagram indicates a second round of ATP hydrolysis.

on one side of the Mcm2–7 ring, suggesting CMG may encircle both single strands at a forked junction (Costa *et al.*, 2011). Further studies will be needed to determine if this is the case. The Mcm2–7 hexamer contains the motor subunits, but unlike DnaB, the Mcm2–7 ring contains a gap, between subunits

Mcm2 and Mcm5 (Costa *et al.*, 2011; Lyubimov *et al.*, 2012). The archaeal Mcm is a homohexamer (and sometimes double hexamer) that does not appear to contain a gap between subunits; and it is an active helicase without accessory factors (Beattie and Bell, 2011; Bell and Botchan, 2013; Chia *et al.*, 2010; Chong *et al.*, 2000; Graham *et al.*, 2011; Pan *et al.*, 2011; Sakakibara *et al.*, 2009). However, archaeal cells contain sequence homologs of the GINS and Cdc45, and thus may form a CMG complex like eukaryotes (Makarova *et al.*, 2012).

Most of the knowledge about how AAA+ hexameric helicases function is derived from studies of SV40 T-antigen and papilloma virus E1 helicases. These helicases are based on the AAA+ domain and form homohexameric rings, suggesting they share a common ancestor with the Mcm proteins of eukaryotes and archaea (Chia *et al.*, 2010; Leipe *et al.*, 1999; Makarova and Koonin, 2013). A major breakthrough on the mechanism of these helicases came with the crystal structure of the papilloma virus E1 helicase bound to ssDNA in the presence of ADP (Enemark and Joshua-Tor, 2006). This study revealed a right hand spiral arrangement of ssDNA within the E1 homohexamer. Nucleotide states of subunits within the ring included ATP-like bound subunits, ADP-like bound subunits, and subunits having no bound nucleotide. As with DnaB, the E1 hexamer contains two tiers of rings, an N-terminal tier serving as a collar with a hole for ssDNA to exit, and a C-terminal tier containing the AAA+ domains. The AAA+ domains contain a long loop, each of which binds only one nucleotide per monomer, for a total of six nucleotides per helicase. E1 translocates along ssDNA in the opposite direction to DnaB, but the helical structure implied an 'escort' mechanism of action not unlike the proposed mechanism of DnaB. With each ATP hydrolytic event, the DNA binding loop within the hydrolyzing subunit detaches from ssDNA, then upon rebinding ATP, the subunit reattaches to ssDNA at the top of the helix, after sliding along the six nucleotide long binding site and moving the helicase one base pair in the process. This proposed mechanism is referred to as the 'escort model,' because the ssDNA is escorted through the hexamer by long loops one base at a time.

Primases Are Very Different in Bacteria Compared to Eukaryotes

To initiate DNA chains, cells from all domains of life contain a primase enzyme that synthesizes a short RNA primer on a template ssDNA (Kornberg and Baker, 1992). The difficult step in this process is the formation of the first dinucleotide. This requires the enzyme to have two NTP binding sites, positioning them adjacent to one another to form the first phosphodiester bond. In the cell, rNTPs are at 10- to 100-fold higher concentration than dNTPs and thus use of RNA to initiate synthesis of DNA may reflect the need for a high NTP concentration to bind two NTPs at the same time.

The Bacterial Primase

The sequence and structure of bacterial and eukaryotic primases are completely different (Frick and Richardson, 2001). The structure of bacterial primase, referred to as DnaG, reveals

that it is related to topoisomerases (Figure 6(a); Keck *et al.*, 2000; Podobnik *et al.*, 2000). This folding pattern is referred to as the 'toprim fold,' to reflect this relationship (Aravind *et al.*, 1998). DnaG primase starts chains with a purine and generates RNA primers of 10–12 nucleotides (Rowen and Kornberg, 1978). After primer synthesis, the β clamp is assembled on the primer by the clamp loader and extended into a 1–2 kb Okazaki fragment by the replicative C-family polymerase. RNA primers are removed and filled in by the concerted action of the 5'-3' exonuclease and polymerase activities of Pol I, followed by ligase which seals the fragments together (Kornberg and Baker, 1992).

The Eukaryotic Primase

The eukaryotic primase requires two different subunits, Pri1 and Pri2, which are associated within the four subunit Pol α (Kaguni *et al.*, 1983a). Archaeal primase is composed of two subunits without the additional polymerase and B-subunit of Pol α (Liu *et al.*, 2001; Hubscher *et al.*, 2002). The small subunit (Pri1, p48 kDa in human, PriS in archaea) is the catalytic subunit (Copeland and Wang, 1993; Hubscher *et al.*, 2002; Kaguni *et al.*, 1983a; Kuchta and Stengel, 2010; Liu *et al.*, 2001). The large subunits of archaeal (PriL) and eukaryotic (PriL, p58 in human) primase share limited homology (Kuchta and Stengel, 2010). The large subunit is required, or greatly stimulates priming and it contains an FeS cluster needed for primase function (Klinge *et al.*, 2007; Weiner *et al.*, 2007; Zerbe and Kuchta, 2002). In eukaryotic Pol α , the RNA primer is transferred to the DNA polymerase subunit and extended another 20–25 nucleotides with DNA (Conaway and Lehman, 1982; Kilkenny *et al.*, 2013; Perera *et al.*, 2013). The reason that eukaryotes synthesize an RNA-DNA primer is not fully understood. The RNA-DNA primer is then recruited by PCNA/RFC and extended by Pol δ in a 'Pol α /Pol δ switch' (Tsurimoto and Stillman, 1991). Since DNA polymerase α lacks a proofreading exonuclease, the DNA portion of the primer is efficiently proofread by mismatch repair and Exo I (Hombauer *et al.*, 2011; Liberti *et al.*, 2013). The RNA portion, and some excision of the DNA portion involves limited strand displacement by Pol δ , and the Fen1 5'-3' nuclease or a combination of the Dna2 and Fen1 nucleases depending on the length of strand displacement (Balakrishnan and Bambara, 2013; Stith *et al.*, 2008).

The eukaryotic Pri1 catalytic subunit has sequence similarity to the Pol X family of DNA polymerases (Kirk and Kuchta, 1999), and comparison of their structures show that the 'active site' acidic residues superimpose (Figure 6(b)), indicating that eukaryotic primase probably functions by a two-metal mechanism like DNA polymerases (Augustin *et al.*, 2001). In a departure from eukaryotes, archaeal primases can initiate primers using dNTPs and can even extend them with DNA for one to several kilobases (Bocquier *et al.*, 2001; Liu *et al.*, 2001). However, archaeal primases bind rNTPs much tighter than they bind dNTPs (Lao-Sirieix and Bell, 2004). Importantly, in archaeal cells, Okazaki fragments contain 5' terminal RNA (Matsunaga *et al.*, 2003). Thus in the cell, archaeal primase makes RNA primers. Interestingly, some bacteria contain a LigB protein involved in repair that is

Figure 6 Structures of bacterial and eukaryotic/archaeal primases are unrelated. (a) Structure of *E. coli* DnaG primase and relationship to topoisomerases. homologous to archaeal primase and has similar catalytic activities (Zhu and Shuman, 2005).

The PrimPol Primase

Recent studies have identified a new type of eukaryotic primase-polymerase (primpol) in eukaryotic cells that shares homology to archaeal/eukaryotic primases, yet is a distinct protein (Garcia-Gomez et al., 2013). PrimPol can initiate synthesis using dNTPs or rNTPs, with an apparent preference

for dNTPs, and can extend DNA over common types of oxidative damage, abasic sites, and even UV photoproducts (Bianchi et al., 2013; Garcia-Gomez et al., 2013; Keen et al., 2014; Rudd et al., 2013; Wan et al., 2013). These properties suggest primPol may help nuclear forks to advance over a damaged nucleotide, and in fact some evidence for this has been demonstrated in cellular studies (Bianchi et al., 2013; Mouron et al., 2013). PrimPol is also located inside mitochondria, and gene silencing in cell culture affects mitochondrial replication (Garcia-Gomez et al., 2013). The mitochondrial location suggests that primPol may act in

Figure 7 Single-strand DNA-binding proteins of bacteria and eukaryotes. (a) Model of *E. coli* SSB tetramer-ssDNA complexes based on crystal structure information. SSB is a homotetramer of subunits (colored differently); each subunit has one OB fold. The SSB tetramer has two binding modes, 35 nucleotides bound to two subunits and 65 nucleotides bound to all four subunits. The models of these two modes are reproduced with permission from Figure 1a,b in Roy *et al.* (2007). (b) Illustration eukaryotic RPA composed of three different subunits that have six OB folds. Four OB folds bind DNA, labeled A–D. Three binding modes have been detected: Domains AB, then domains ABC, and finally domains ABCD. See text for details. Reprinted from Roy, R., Kozlov, A.G., Lohman, T.M., Ha, T., 2007. Dynamic structural rearrangements between DNA binding modes of *E. coli* SSB Protein. *Journal of Molecular Biology* 369 (5), 1244–1257, Copyright (2007) with permission from Elsevier.

mitochondrial replication (Garcia-Gomez *et al.*, 2013), but knock out mice survive and thus primpol is not essential. Studies of primpol have only just begun, and caution may need to be exercised, considering that many biochemical studies of primpol utilize Mn^{++} instead of Mg^{++} , and Mn^{++} is known to alter the specificity of DNA polymerases for nucleic acid substrates (Kornberg and Baker, 1992).

Single-Strand DNA-Binding Protein

Single-strand DNA-binding proteins are required in all domains of life and fulfill diverse roles in genome metabolism (Flynn and Zou, 2010). During replication, single-strand DNA-binding protein protects ssDNA from nucleases, removes hairpin blocks, and prevents strand reannealing. Bacterial single-strand DNA-binding protein is a homotetramer referred to as SSB, and in eukaryotes it is a heterotrimer referred to as replication protein A (RPA) (Kornberg and Baker, 1992). The sequence and structure of bacterial SSB and eukaryotic RPA indicate that they do not share a common ancestor (Leipe *et al.*, 1999). However, both SSB and RPA bind ssDNA using OB folds, a widespread ‘oligonucleotide and oligosaccharide binding’ motif (Murzin, 1993). The sequence of OB folds can vary considerably, and range from 70 to 150 amino acids. OB folds are comprised of a closed β barrel consisting of 5 tightly coiled antiparallel β sheets with a helix at one end and the

binding site at the other end (Murzin, 1993). OB folds often bind ssDNA but they can also bind RNA and protein.

The Bacterial SSB

The structure of the *E. coli* SSB homotetramer reveals four OB folds, one per monomer, illustrated in Figure 7(a) (Raghuathan *et al.*, 2000). SSB can bind ssDNA in two modes that occupy either 35 or 65 nucleotides (Roy *et al.*, 2007). RPA contains six OB folds, although only four OB folds bind to ssDNA (Figure 7(b); Bochkarev and Bochkareva, 2004; Fanning *et al.*, 2006; Wold, 1997). The RPA1 subunit (p70 in human) contains four OB folds; the OB fold near the N-terminus binds a checkpoint response signaling factor, and the other three bind ssDNA, designated A, B, and C in order of decreasing affinity. RPA2 (p32 in human) also contains a ssDNA binding OB fold, designated D. RPA3 (p14 in human) contains an OB fold that interacts with RPA2.

The Eukaryotic RPA

Unlike bacterial SSB, the OB folds of RPA are connected by flexible linkers that are substantially disordered in the RPA trimer, making structure determination of intact RPA elusive. Regardless of the inherent flexibility in RPA, it binds ssDNA very tightly with an affinity of 10^{-9} – 10^{-10} M (Kim *et al.*, 1994). Notably, the asymmetric structure of RPA binds ssDNA

with a definite 5'-3' polarity, and can impart this directional information to other proteins (de Laat *et al.*, 1998; Iftode and Borowiec, 2000). Biochemical study indicates that RPA can bind ssDNA in three states (illustrated in Figure 7(b)): (1) binding of OB folds A and B occludes about 10 nucleotides, (2) binding of OB folds A, B and C occludes 12–23 nucleotides, and (3) binding of the four OB folds occludes 28–30 nucleotides (Arunkumar *et al.*, 2003; Bastin-Shanower and Brill, 2001; Bochkareva *et al.*, 2002; Kolpashchikov *et al.*, 2001; Kumaran *et al.*, 2006). The functional significance of different conformers is not certain. There also exist different varieties of RPA subunits that form alternative RPA complexes; their functions are insecure, and lie outside of replication (Flynn and Zou, 2010). For example, telomere maintenance requires an alternative form of RPA (Flynn and Zou, 2010).

Comparison of Bacterial and Eukaryotic Replisomes

The proteins described in this review must interdigitate their actions for efficient replication of the DNA duplex. Information of how bacterial replication proteins work together largely come from studies of reconstituted replisomes in the *E. coli* system and its bacteriophages T4 and T7 (Benkovic *et al.*, 2001; Duderstadt *et al.*, 2014; Geertsema and van Oijen, 2013; Johnson and O'Donnell, 2005). Our current knowledge of eukaryotic replisome function largely stems from numerous genetic and cellular-based studies (Bell and Kaguni, 2013; Burgers, 2009; Heller *et al.*, 2011; Kunkel, 2011; Siddiqui *et al.*, 2013). *In vitro* studies of the eukaryotic replisome have centered around the SV40 virus, which uses host proteins except for the viral T-antigen helicase (Fanning and Zhao, 2009; Sowd and Fanning, 2012). Recently a reconstituted system of cellular replication using CMG helicase, RFC, PCNA, RPA and the DNA polymerases has been reported (Georgescu *et al.*, 2014).

In both bacteria and eukaryotes, the helicase is tightly associated with DNA at the replication fork. In contrast, DNA polymerases within replisomes are less tightly associated to replication fork DNA. One reason for this may lie in the fact that replisomes encounter DNA lesions that require other DNA polymerases to traverse them (Indiani *et al.*, 2009; Johnson *et al.*, 2007; Yang *et al.*, 2004; Zhuang *et al.*, 2008). DNA lesions occur frequently in cells due to endogenous attack of DNA by water, reactive oxygen species generated by oxidative metabolism, as well as exogenous genotoxic insults. DNA lesions are difficult for the high fidelity replicative DNA polymerases to pass, stopping a replication fork. One process that enables replication forks to bypass DNA lesions is exchange of the replicative polymerase with one of several translesion synthesis DNA polymerases (TLS Pols), low fidelity enzymes that can extend DNA across a template lesion (Goodman and Woodgate, 2013; Yang, 2014). Insight into polymerases exchange during replication came from studies in the T4 system which showed that two T4 DNA polymerases can trade places on the same sliding clamp while the replisome is moving (Yang *et al.*, 2004). Studies in bacteria demonstrated that TLS polymerases bind the β clamp and can trade places with Pol III stalled on template DNA (Indiani *et al.*, 2009). In this processes, the clamp can accommodate two DNA polymerases at

once, at least transiently. In eukaryotes, the PCNA clamp is ubiquitinated in response to DNA damage (Hoegge *et al.*, 2002), which is associated with TLS DNA polymerase exchange on PCNA (Garg and Burgers, 2005b; Zhuang *et al.*, 2008). The emerging view is that replisomes are not a single entity, but are highly dynamic and more malleable than ever before envisioned (Langston *et al.*, 2009).

The Bacterial Replisome

The central replication proteins of *E. coli* are associated in a particle organized by the clamp loader as illustrated in Figure 8(a) (O'Donnell *et al.*, 2001). The central organizer of this 'replisome' is a trimer of three identical τ subunits in the clamp loader, encoded by the *dnaX* gene (Johnson and O'Donnell, 2005). The C-terminal sequence of τ is not required for the clamp loading reaction, but is essential to cell viability and encodes two domains that extrude from the collar of the clamp loader. These three C-terminal regions bind one DnaB helicase and three molecules of Pol III core. For the last 30 years the paradigm of replisome structure has included only two DNA polymerases (Kornberg and Baker, 1992), and viral systems may, in fact, utilize only two polymerases (Chen *et al.*, 2013). However, the triple polymerase structure of the *E. coli* replisome has been confirmed biochemically and by *in vivo* single-molecule studies of living cells (Georgescu *et al.*, 2011; McInerney *et al.*, 2007; Reyes-Lamothé *et al.*, 2010). Single-molecule studies of the *E. coli* replisome, both *in vitro* and *in vivo*, reveal that all three polymerases are functional at a fork, one for leading strand synthesis, and the other two co-operate to extend the numerous Okazaki fragments (Georgescu *et al.*, 2011; Lia *et al.*, 2012).

The connection between Pol III and DnaB, via τ , results in a 10- to 20-fold stimulation of helicase unwinding (Kim *et al.*, 1996). This stimulation requires an active polymerase, not just binding to τ , making it unlikely that stimulation is derived from a simple allosteric change induced by binding τ (Dallmann *et al.*, 2000). Presumably, the polymerase–helicase connection enables transfer of the energy of polymerization to the helicase. Indeed, functional coupling of the leading polymerase to the helicase generalizes to both phage T4 and phage T7 systems (Dong *et al.*, 1996; Kulczyk *et al.*, 2012; Manosas *et al.*, 2012).

The single clamp loader within the replisome assembles clamps onto both the leading and lagging strands (Turner *et al.*, 1999). Once associated with a β clamp, Pol III is highly processive in DNA synthesis and can extend DNA thousands of nucleotides at a rate exceeding 500 nucleotides, consistent with *in vivo* studies that demonstrate an average rate of the *E. coli* replication fork to be 650 nucleotides (Breier *et al.*, 2005; Yao *et al.*, 2009). In some bacteria, including *E. coli*, the *dnaX* gene produces two proteins, the full length τ , and a smaller γ subunit that is truncated by a translational frameshift. These cells contain a second clamp loader containing three γ subunits instead of three τ subunits. The τ and γ clamp loaders function with equal efficiency in clamp loading (McInerney *et al.*, 2007), but only τ complex binds polymerase and helicase (Gao and McHenry, 2001). The γ complex is proposed to load β clamps onto DNA for the many different DNA

Figure 8 Proposed replisome architectures in bacteria and eukaryotes. Left: The *E. coli* replisome. The DnaB hexamer (purple) encircles the lagging strand. Primase (blue) transiently binds DnaB to produce RNA primers. The clamp loader (green) binds DnaB and three molecules of Pol III (yellow). Sliding β clamps are shown in red. SSB (light blue) coats ssDNA on the lagging strand. The leading strand Pol ϵ binds CMG through contact to Psf1 of the GINS complex within CMG. Ctf4 is a trimer that binds the Sld5 subunit of GINS and the Pol1 subunit of Pol α polymerase/primase. Ctf4 has a weak connection to Pol δ . Both Pol ϵ and Pol δ can function with PCNA (red). The clamp loader, RFC, is not known to be connected to the replisome. The ssDNA on the lagging strand is bound by the RPA heterotrimer.

metabolic processes that utilize β outside the context of a DNA replication fork (McInerney *et al.*, 2007; Yao and O'Donnell, 2009).

Another general feature of *E. coli* and phages T4 and T7 is the association of primase with the helicase in order for primase to become active (Frick and Richardson, 2001; Kornberg and Baker, 1992). The requirement that primase associate with helicase localizes RNA primers to replication forks where they are needed. *E. coli* DnaG primase transiently interacts with DnaB to form RNA primers of 10–12 nucleotides. The T4 primase does likewise, forming 5-nt RNA primers. T7 primase is a separate domain(s) within the gp4 helicase and generates 4mer RNA primers at unique sequences.

Due to the antiparallel structure of duplex DNA, replisomes synthesize one strand (lagging) in the opposite direction of the other (leading strand). The leading strand is continuously extended in the direction of replication fork movement, while the lagging strand is discontinuous and made as a series of numerous Okazaki fragments, necessitated by the unidirectional nature of DNA polymerases. Each Okazaki fragment is initiated by an RNA primer. Extension of RNA primers into Okazaki fragments results in DNA loops, due to the fact that the lagging polymerase remains in contact with the replisome. This was first proposed by Bruce Alberts in the T4 system, and Okazaki loops were referred to as 'trombone loops' because the DNA loops mimic the motion of a

trombone slide while the instrument is played (Sinha *et al.*, 1980). DNA looping has been observed in the electron microscope in the phage T4 and T7 systems (Nossal *et al.*, 2007; Park *et al.*, 1998). DNA looping has also been observed in real-time by single-molecule studies in the T7 system (Hamdan *et al.*, 2009). Single-molecule studies of the *E. coli* replisome, performed in a flow cell in the absence of added polymerase, clamp loader, and helicase, also confirm that DNA loops must form because the replisome synthesizes both strands at an average of 86 kb before dissociating (Yao *et al.*, 2009). Hence, the helicase, polymerase, and clamp loader components form a tightly associated replisome that remains intact during movement, and therefore numerous Okazaki fragment loops must be formed during fork progression (Breier *et al.*, 2005).

The fact that the β clamp endows Pol III with exceptional processivity, well above the length of an Okazaki fragment, raises the question of how the lagging strand polymerase dissociates from DNA upon completing an Okazaki fragment. The release step is triggered by multiple processes, all of which require polymerase to detach from the clamp, leaving the clamp on DNA (O'Donnell, 1987; Yang *et al.*, 2006). The clamp loader repeatedly loads clamps onto RNA primers as they are produced by primase, enabling the lagging strand polymerase to reassociate with a new clamp for each Okazaki fragment. This mechanism of polymerase hopping among clamps was initially

demonstrated in *E. coli* (O'Donnell, 1987; Studwell, *et al.* 1989; Stukenberg *et al.*, 1994), and has also been shown to occur in the T4 system (Hacker and Alberts, 1994).

The mechanism of polymerase release from an Okazaki fragment has been examined in the *E. coli*, T4 and T7 systems. In the context of a working T4 replisome, the lagging strand polymerase is often 'signaled' to release from an Okazaki fragment before the fragment has been completed, leaving a ssDNA gap to be filled in by soluble polymerases (Yang *et al.*, 2006). This 'signal release' of polymerase before completing an Okazaki fragment generalizes to *E. coli* and T7, and is associated with formation of a new primed site. Signal release may be triggered by primase, the new primed site, a new clamp assembled on the primed site, or build up of torsional stress caused by coupled leading/lagging strand synthesis (Georgescu *et al.*, 2011; Hamdan *et al.*, 2009; Kurth *et al.*, 2013; Yang *et al.*, 2006). There also exists a second type of polymerase release, called 'collision release,' because the Okazaki fragment is extended to completion and the polymerase collides into the 5' terminus of the previous Okazaki fragment (Hacker and Alberts, 1994; O'Donnell, 1987; Stukenberg *et al.*, 1994). Dissociation of polymerase from DNA during collision release is a process that is intrinsic to the DNA polymerase and does not require other factors (Georgescu *et al.*, 2009). Both signal release and collision release occur during replisome progression (Duderstadt *et al.*, 2014).

The Eukaryotic Replisome

Pol α was the first eukaryotic replicative DNA polymerase to be purified and characterized (Kaguni *et al.*, 1983b). Identification of a primase activity within the four subunit holoenzyme in Bob Lehman's group (Conaway and Lehman, 1982) was a remarkable surprise, as never before had an enzyme contained both primase and polymerase in one tight complex. Another huge advance was development of the *in vitro* SV40 DNA replication system (Li and Kelly, 1984). The SV40 virus encodes only one replication protein, the T-antigen helicase; all the rest of its replication proteins are encoded by the cell. Intensive studies of the SV40 system in the Kelly, Stillman, and Hurwitz laboratories identified Pol δ , RFC, PCNA and RPA (Fanning and Zhao, 2009; Sowd and Fanning, 2012). Upon discovery that Pol δ was a replicative enzyme, Pol α was thought to replicate the lagging strand (since it makes primers) and that Pol δ replicated the leading strand. But further work showed that Pol δ replicated both strands while Pol α served as a primase (Stillman, 2008). Genetic studies soon thereafter identified Pol ϵ as a third replicative cellular polymerase, while SV40 did not utilize Pol ϵ , indicating that SV40 did not replicate quite the same as cellular replisomes (Zlotkin *et al.*, 1996). The question of which strands Pol δ and Pol ϵ operate on during chromosome replication was unresolved for many years. Cleaver genetic studies by Tom Kunkel's group and his collaborators have now conclusively shown that Pol ϵ replicates the bulk of the leading strand, while Pol δ replicates the lagging strand (Kunkel and Burgers, 2008; Pursell *et al.*, 2007).

At the head of the replisome is the 11 subunit CMG helicase (Costa *et al.*, 2011; Ilves *et al.*, 2010; Kang *et al.*, 2012;

Moyer *et al.*, 2006). As discussed earlier in this review, CMG tracks along the leading strand, and CMG is known to bind numerous proteins. Proteins that bind CMG have been identified by epitope tagging CMG subunit genes, followed by antibody pull-outs from cells to identify CMG interactive proteins by mass spectrometry (Gambus *et al.*, 2006). The protein assemblage thus identified is referred to as the replisome progression complex (RPC), and includes CMG, Ctf4, Mcm10, Fact (a nucleosome remodeling complex), Topo I, and three proteins involved in the DNA damage checkpoint (Csm3, Mrc1, and Tof1). Interestingly, RPC does not contain DNA polymerases, implying that DNA polymerases are not tightly associated with CMG. This may not be surprising given the inability to isolate helicase-polymerase complexes in bacterial systems, even though the helicase and polymerase are known to interact. However, when CMG is isolated under mild conditions Pol α co-purifies with RPC (Gambus *et al.*, 2009) and this association requires the presence of Ctf4, an oligomer that has long been known to bind Pol α (Miles and Formosa, 1992). The Ctf4 oligomer also binds to CMG through the Sld5 subunit of GINS (Simon *et al.*, 2014). Interestingly, the GINS complex binds to Pol ϵ through the Psf1 subunit of GINS (Bermudez *et al.*, 2011; Sengupta *et al.*, 2013). This connection implies that Pol ϵ binds CMG directly, which is somewhat analogous to bacterial replisomes in which the leading polymerase binds the helicase during coupled polymerase-helicase fork progression. The rate of eukaryotic replication forks is much slower than in bacteria and archaeal cells. In budding yeast, fork progression is estimated at 30–60 bp/s (Raghuraman *et al.*, 2001; Sekedat *et al.*, 2010; Yabuki *et al.*, 2002), 10- to 20-fold slower than in *E. coli*.

Interestingly, the crystal structure of Ctf4 shows it is a homotrimer (Simon *et al.*, 2014). Hence, it is tempting to speculate that Ctf4 may be the scaffolding equivalent of the bacterial τ subunit, a trimer that links the helicase with DNA polymerases (compare Figures 8(a) and 8(b)). Indeed, a weak interaction of Pol δ with Ctf4 has been reported (Bermudez *et al.*, 2010). Although Ctf4 is not essential in budding yeast, Ctf4 is essential in fission yeast and other eukaryotes. Mcm10 is essential to cell viability and it binds to Pol α , although the exact function of Mcm10 in DNA replication remains unknown (Warren *et al.*, 2009). Some studies suggest Mcm10 is required during origin activation, while other studies indicate Mcm10 acts at a late stage, when replisomes are assembled (Heller *et al.*, 2011; Kanke *et al.*, 2012; Siddiqui *et al.*, 2013; van Deursen *et al.*, 2012). The Csm3, Tof1, Mrc1 proteins of the RPC are not essential, but their involvement in the checkpoint response suggests they may regulate replisome function in response to DNA damage. It is likely that many other proteins will be shown to move and function with replication forks in future studies.

It seems likely that the eukaryotic replisome is more dynamic than the bacterial replisome. The affinity of Ctf4 for CMG helicase appears stable to glycerol gradient analysis, implying a tight connection between these two proteins (Kang *et al.*, 2013). But the affinities of the polymerases ϵ , α , and δ to the replisome appear much weaker (Gambus *et al.*, 2009; Bermudez *et al.*, 2010). Therefore the eukaryotic polymerase may loosely interact with the replisome during fork progression, rather than forming a stable connection between the

leading and lagging strand polymerases as observed in the bacterial replisome in which the τ subunit tightly binds three molecules of Pol III in a stable fashion. Looser connections of the eukaryotic polymerases with the replisome implies that the DNA polymerases are more dynamic and form transient connections to Ctf4 and/or CMG subunits, producing a dynamic replisome. It is possible that a more dynamic replisome, with more transient polymerase connections enables translesion synthesis DNA polymerases to enter the replisome to help the replisome move forward if it encounters a template lesion. Dynamic polymerase action in the replisome may also facilitate the many protein exchanges required in the confines of short Okazaki fragments during their maturation prior to ligation. For example, eukaryotic Okazaki fragments only average 160 bp, and many operations occur within this short section of DNA. First Pol α makes a RNA-DNA primer, then RFC loads PCNA onto the primed site. Pol δ then extends the short Okazaki fragment and a nucleosome is thought to assemble on the new Okazaki fragment even before fragments are sealed. The RNA-DNA primers must also be displaced and removed by nuclease action before ligase can seal two Okazaki fragments together. Thus a dynamic replisome with DNA polymerases capable of coming on and off the replisome may be important to make way for these many actions within a short region of DNA.

DNA looping has served as a paradigm in the bacterial replication field. However, the more dynamic a replisome, the less likely that connections among replisome components will create DNA loops during lagging strand synthesis. It is interesting to note that DNA loops have no known function; they are simply documented to exist in bacterial systems. Perhaps DNA loops are simply an artifact of the use of identical polymerases on leading and lagging strands, in which the leading polymerase binds the helicase, which itself is an assembly of identical subunits. Hence, the lagging strand polymerase may contact the helicase simply as a consequence of the interactions that evolved to enhance function on the leading strand, resulting in DNA loops during lagging strand synthesis. DNA looping is a very low energetic process. Assuming that DNA loops carry no energetic penalty, there would be no selective pressure to prevent their formation on the lagging strand.

The mechanistic basis for the asymmetric assembly of different DNA polymerases onto their respective leading and lagging strands of the eukaryotic fork has recently been determined (Georgescu *et al.*, 2014). CMG helicase stabilizes Pol ϵ on the leading strand, enabling processive DNA synthesis by Pol ϵ even in the absence of PCNA. But Pol δ is not stabilized by CMG, and acts distributively on the leading strand. The distributive behavior of Pol δ with CMG on the leading strand contrasts sharply with the high processivity demonstrated by yeast Pol δ -PCNA on primed ssDNA (Langston and O'Donnell, 2008). The stable function of Pol ϵ with CMG, and unstable function of Pol δ with CMG, likely underlies the basis by which Pol ϵ is directed to the leading strand. Protein binding experiments show that Pol δ binds PCNA much tighter than Pol ϵ (Chilkova *et al.*, 2007), and competition experiments show that Pol δ effectively out-competes Pol ϵ for use of PCNA clamps on primed ssDNA (Georgescu *et al.*, 2014). The greater affinity of Pol δ for PCNA clamps compared

to Pol ϵ may explain how Pol δ is selected for function on the lagging strand over Pol ϵ . However, it is worth noting that the human Pol δ is not highly processive with PCNA (Hu *et al.*, 2012), and therefore further studies will be needed to determine if these principles generalize to human replisomes.

Fork progression in eukaryotes is regulated by the DNA damage checkpoint response. This pathway recognizes the presence of DNA lesions and activates a kinase that phosphorylates a variety of targets. Among the targets of these kinases are Mcm and GINS subunits of CMG (Cortez *et al.*, 2004; Ilves *et al.*, 2012; Segurado and Diffley, 2008). Activity assays of phosphorylated CMG demonstrate that helicase action is down-regulated in response to phosphorylation (De Piccoli *et al.*, 2012; Ilves *et al.*, 2012). Cell-based studies indicate that replication forks stop, or move slowly upon activation of the DNA damage checkpoint (Labib and De Piccoli, 2011). However, phosphorylation may not be the only explanation for how the replisome is halted upon DNA damage, and recent biochemical studies provide another possibility (Bruck and Kaplan, 2013). The Cdc45 subunit of CMG contains a ssDNA binding activity that requires about 40 nucleotides of ssDNA. Mutation of the DNA interactive residues in Cdc45 yields a Cdc45 mutant with reduced affinity for ssDNA (Bruck and Kaplan, 2013). Interestingly, study of cells with this Cdc45 ssDNA binding mutant indicate that replication forks no longer stop upon activation of the DNA damage checkpoint (Bruck and Kaplan, 2013). These findings have been interpreted as follows. When the replication fork encounters a leading strand lesion, Pol ϵ stops at the lesion, but CMG continues unwinding. When 40 nucleotides of ssDNA are exposed, Cdc45 binds the ssDNA and stops the fork. The Cdc45 DNA binding mutant is unable to bind ssDNA and stop the fork upon encounter with DNA damage. Further study will be needed to develop a more complete understanding of how replisomes are controlled by the DNA damage checkpoint. In addition to phosphorylation in response to DNA damage, numerous replication fork proteins are phosphorylated in a cell cycle specific fashion, including Pols α , δ , and ϵ , RPA, and particular Mcm subunits (Errico and Costanzo, 2012; Gangavarapu *et al.*, 2011; Olson *et al.*, 2006; Sheu *et al.*, 2014; Sheu and Stillman, 2010). In most cases, the exact kinases and the roles these modifications are not yet understood.

What Is Needed for the Future?

The process of replication has been studied for many decades, and the basic outline of the process is understood. The facts that replication requires 5'-3' DNA polymerases, dNTPs, a proofreading 3'-5' exonuclease, hexameric helicase, RNA primase, and SSB to replicate DNA in a semi-discontinuous manner required the effort of numerous labs for about 30 years after the discovery of the DNA structure. Identification of accessory protein function as clamps and clamp loaders, also a universal feature of cells, took another 20 years. The organization of these proteins, and how they deal with DNA lesions is also reasonably well understood, although significant details about the mechanism and how the

replisome interfaces with repair and recombination is still in progress.

While it may seem that the major questions about bacterial replication are answered, this is certainly not the case for eukaryotic cells. New proteins that act at eukaryotic replication forks are being identified at a rapid pace. The functional consequences of cell cycle specific phosphorylation is not understood, nor are the targets and function of other modifications such as acetylation, ubiquitination, and sumoylation, most of which are not covered in this review. It remains unknown how eukaryotic replisomes progress through nucleosomes, especially highly condensed chromatin. Furthermore, episomal modifications of nucleosomes that regulate the transcriptome of a cell must be preserved during development of a multicellular organism, and the mechanism by which 'marked nucleosomes' are transferred from the parental duplex to sister chromatids is essentially unexplored. The process of sister chromatid cohesion is also intimately involved with the replication process. It is presumed that the replisome progresses through cohesion rings, although whether this occurs, and if so, what factors are required, is not at all clear. The process of assembly of cohesion rings is also still unknown. There exist at least three alternative clamp loaders in which the RFC1 subunit is exchanged for another protein and one of these alternative clamp loaders is genetically linked to the process of cohesion, but no data exists to suggest what special function this alternative clamp loader performs for this action.

Replisomes are assembled at origins in a highly regulated multistep process, not reviewed here. It is during this origin activation process that the CMG is assembled. First the Mcm rings are placed onto duplex DNA and at some point, GINS and Cdc45 are brought into the Mcm complex and the complex must transit from encircling duplex DNA to encircling leading strand ssDNA. Reconstitution of this process and an understanding of how the many assembly factors function is shrouded in mystery. Reconstitution of a functioning eukaryotic replisome from pure proteins also remains an important goal. Study *in vitro* of these multiprotein reactions will be required to gain detailed insight into the structure and function of the many proteins that regulate origin firing and perform the mechanics of replication fork progression. Many repair processes are also known to require replication fork proteins, sometimes occurring at the fork itself. For example, break-induced repair involves the initiation of a functional fork at a DNA break that continues for many kilobases until the end of a linear chromosome. This process appears to require many of the same proteins that move normal replication forks, yet it is mutagenic and its exact mechanism has only begun to be explored. Eukaryotes also have telomeres that require the telomerase polymerase, and several other proteins, including some of those at the fork. Many human diseases are also the result of defects in one of these many processes. We can hope that some of the insights gained from a greater understanding of their mechanistic basis will prevent, or at least treat some of these diseases. These, and many other important questions will require intensive genetic, cellular, biochemical, and structural studies. It is only reasonable to expect that the answers to these important questions will be very exciting, but also will take many years of research from numerous bright and energetic scientists.

Glossary

Exonuclease An enzyme that catalyzes the hydrolysis of nucleic acids from the ends of the molecule.

Heterodimer A molecule composed of two different, simpler molecules.

Homodimer A molecule composed of two identical, simpler molecules.

Nucleoprotein A substance composed of DNA and protein.

Polymerase An enzyme that catalyzes the formation of a long-chain DNA molecule by linking DNA nucleotides together.

Retrotransposon A segment of DNA which goes through an RNA intermediate prior to inserting DNA copies of itself into the genome of the same cell.

Reverse transcriptase (RT) A polymerase that catalyzes the formation of DNA from an RNA template in the process of reverse transcription.

Ribonucleoprotein A substance composed of RNA and protein.

Senescence When a cell is no longer capable of dividing but still alive and metabolically active.

Somatic Of the body and distinguished from the germ line or stem cells.

Telomeres

In the late 1930s, Hermann Muller discovered that the native ends of linear eukaryotic chromosomes are functionally distinguished from chromosome breaks generated by X-ray irradiation. Muller coined the term 'telomere,' a combination of the Greek words 'telo-' and '-mere' meaning end part, to designate the distinctive and protective terminal portion of the chromosome. Shortly thereafter, Barbara McClintock described similar findings in maize with dicentric chromosomes – chromosomes with two centromeres – which are extremely unstable due to the high frequency of chromosome breakage and fusion events (McClintock, 1941). During cell division, dicentric chromosomes often result in chromosomal bridges between daughter cells and subsequent chromosome breaks leading to additional events of fusion and dicentric chromosome formation. This breakage–fusion–bridge cycle can be stopped in embryonic cells where the broken chromosome ends are healed by *de novo* addition of protective telomeres.

The findings of Muller and McClintock set the foundation for telomere biology years before DNA was known as the genetic material of inheritance.

The End-Replication Problem

The inability of conventional DNA polymerases to fully replicate the ends of linear DNA was recognized as 'the end-replication problem' in the early 1970s (Watson, 1972; Olovnikov, 1973). DNA polymerases synthesize DNA in a 5' to 3' direction and require a free 3'-hydroxyl group for the catalysis of nucleotide addition. The 3'-hydroxyl group is initially provided by an RNA primer which is later degraded and in-filled with DNA. It was postulated that the end-most RNA primer cannot be in-filled with DNA, which in theory results in DNA products shorter than the parental DNA each time the cell divides (Figure 1). However, it was later understood that eukaryotic chromosome ends have 3'-overhangs of

The length and shortening rate of telomeres is viewed as a molecular clock that determines the replicative capacity of somatic cells. Human somatic cells continuously cultured outside of the body eventually senesce and lose viability. Early work by Leonard Hayflick showed that terminally differentiated somatic cells had a limited number of cell divisions possible, termed the 'Hayflick limit' (Hayflick, 1965). The progressive loss of telomeric DNA from chromosome ends eventually induces cell senescence and is the limiting factor for the number of cell divisions possible (d'Adda di Fagagna *et al.*, 2003).

Telomeres are nucleoprotein complexes composed of telomeric DNA that consists of a vast array of highly repetitive short DNA sequences. In the late 1970s, Elizabeth Blackburn sequenced telomeric DNA from the free-living unicellular eukaryote *Tetrahymena thermophila* that uniquely contains millions of copies of linear minichromosomes amplified during its vegetative growth phase. These amplified linear minichromosomes are appended with telomeric DNA at the ends, providing a rich sample source for sequencing telomeric DNA. Blackburn discovered that *Tetrahymena* telomeric DNA contains hundreds of copies of the repeated sequence 'TTGGGG,' later termed the 'G-strand' in reference to the high propensity of guanosine nucleotides (Blackburn and Gall, 1978). The complementary 'C-strand' was named for the high incidence of cytosine nucleotides. Human telomeric DNA contains the repeat sequence 'TTAGGG,' which is slightly different from *Tetrahymena* (Moyzis *et al.*, 1988; Figure 2). The telomeric DNA sequence TTAGGG is not unique to humans. Rather, it is found throughout all known vertebrate species as well as select species ranging from marine invertebrates to fungi to plants to protozoans (Meyne *et al.*, 1989; Podlevsky *et al.*, 2008). While the length of telomeric DNA in *Tetrahymena* is only hundreds of base-pairs, in humans it is 10 000–15 000 base-pairs with a 3' G-strand overhang of approximately 200 nucleotides in length (Makarov *et al.*, 1997). In mammals, the 3' G-strand overhang is protected by invading the double-stranded telomeric DNA, and forms a D-shaped loop structure, termed a T-loop (Griffith *et al.*, 1999). Telomeric DNA is bound by unique groups of proteins which distinguish telomere ends from damage-induced chromosome breaks.

Figure 1 The end-replication problem results in DNA loss. Conventional DNA polymerases are unable to fully replicate the ends of linear eukaryotic chromosomes leading to shorter DNA products than the parental DNA strands. The lagging strand terminal-most RNA primer (red) cannot be in-filled with DNA resulting in a slightly shorter DNA strand (blue). In contrast, leading strand synthesis generates a blunt-end which is processed by exonucleases Apollo and Exo1 and results in a much shorter DNA product (blue).

Figure 2 Mammalian telomeric DNA is coated by the Shelterin protein complex. The Shelterin complex is composed of three DNA binding proteins(TRF1 (blue), TF2 (violet), and POT1 (red)) and three associated proteins. RAP1 (green) binds selectively to TRF2 and not TRF1, while TIN2 (yellow) and TPP1 (orange) bridge the single-stranded and double-stranded regions of the telomere.

Telomeric Proteins

In mammals, telomeric DNA is coated by the Shelterin protein complex. The Shelterin complex is composed of six proteins: three directly bind to telomeric DNA and are in turn bound by the remaining three proteins (de Lange, 2005; Figure 2). Shelterin proteins are continuously and specifically associated with telomeric DNA throughout the cell cycle as opposed to numerous additional proteins which transiently bind to mammalian telomeric DNA. The first Shelterin proteins identified were aptly termed Telomeric Repeat-binding Factors 1 and 2 (TRF1 and TRF2, respectively). TRF1 was identified by purification of human cell extracts and later characterization revealed TRF1 bound telomeric DNA through a unique DNA binding 'Myb' sequence (Zhong *et al.*, 1992; Chong *et al.*, 1995). A search for this unique Myb sequence in the human proteome identified TRF2, a protein highly similar in sequence and structure to TRF1 (Bilaud *et al.*, 1997; Broccoli *et al.*, 1997). TRF1 and TRF2 bind double-stranded telomeric DNA as homodimers – protein complexes composed of two copies of the same protein (Figure 2). Despite the immense similarity between these two proteins, TRF1 and TRF2 cannot form heterodimers. TRF1 and TRF2 homodimers specifically recognize double-stranded telomeric DNA through the nine base-pair sequence 'TTAGGGTTA' (Choi *et al.*, 2011). The last Shelterin direct telomeric DNA binding protein, termed Protection Of Telomeres 1 (POT1) was identified as binding single-stranded telomeric DNA located in the 3' G-strand overhang and recognizes the 10 nucleotide sequence 'TTAGGGTTAG' (Baumann and Cech, 2001; Choi *et al.*, 2011; Figure 2).

Telomeric DNA binding by TRF1, TRF2, and POT1 is necessary for the remaining three Shelterin proteins to associate with telomeric DNA (Figure 2). Human Repressor/Activator Protein 1 (RAP1) binds specifically to TRF2 and not to its highly similar counterpart TRF1 (Li *et al.*, 2000). While RAP1 forms a complex with TRF2, this complex is not essential for TRF2 to bind telomeric DNA. Instead, RAP1 functions to prevent inappropriate interactions between neighboring telomeres (Martinez *et al.*, 2010). In the absence of RAP1, these inappropriate telomere interactions induce telomere fragility and breaks which increase the rate of telomere shortening. The last two Shelterin proteins function as molecular bridges, connecting the disparate and physically separate Shelterin protein components (Figure 2). TRF1- and TRF2-interacting nuclear protein 2 (TIN2) function as the central link between the numerous copies of TRF1 and TRF2 proteins which coat double-stranded telomeric DNA (Kim *et al.*, 1999). TIN2 and POT1-interacting protein 1 (TPP1), as the name implies, interacts mutually with POT1 and TIN2 (Houghtaling *et al.*, 2004; Liu *et al.*, 2004; Ye and de Lange, 2004). TPP1 connects single-stranded and double-stranded telomeric DNA together allowing for interaction and communication between these distinct regions of the telomere (Figure 2). The interactions between these unique Shelterin protein components are essential for the overall structure of the telomere and chromosome stability.

Yeast telomeres have two distinct telomeric protein complexes, one specific for double-stranded telomeric DNA and the other for the single-stranded region. The yeast double-stranded telomeric DNA binding complex is formed by the yeast variant of RAP1 and its binding partner proteins RAP1-

Interacting Factors 1 and 2 (RIF1 and RIF2, respectively) (Conrad *et al.*, 1990; Hardy *et al.*, 1992; Wotton and Shore, 1997). Unlike mammalian RAP1, the yeast RAP1 protein directly binds to double-stranded telomeric DNA. Yeast single-stranded telomeric DNA is bound by the three protein complex composed of Cdc13, Stn1, and Ten1, commonly referred to as the CST complex (Lin and Zakian, 1996; Nugent *et al.*, 1996; Grandin *et al.*, 1997, 2001). Stn1 and Ten1 bind to Cdc13 which directly binds single-stranded telomeric DNA. The CST complex is important for regulating the exonucleases responsible for 3' G-strand overhang length. The loss of the CST complex results in an exacerbated C-strand degradation, producing longer 3' G-strand overhangs. A human variant of the CST complex was found to associate with human telomeric DNA and function similarly for regulating the length of the 3' G-strand overhang (Miyake *et al.*, 2009). While the yeast CST complex represses C-strand degradation, the human variant promotes C-strand in-fill (Wang *et al.*, 2012). The human CST complex promotes the association of DNA polymerase alpha (pol α) to the telomere for the in-fill of the C-strand following G-strand extension by the telomerase enzyme (Figure 2).

Telomeric Repeat-Containing RNA

Telomeres were initially viewed as transcriptionally silent, packed into the higher-order heterochromatin structure. It was later discovered that the C-strand of the telomere is used as template for transcription of the long non-coding RNA, termed telomeric repeat-containing RNA (TERRA), which as the name suggests contains telomeric DNA repeat sequences. TERRA has been identified within distantly related species, ranging from vertebrates to yeasts to plants, and is actively transcribed from approximately 25% of the telomeres within a cell (Azzalin *et al.*, 2007). Human TERRA is highly heterogeneous, varying in length from 100 nucleotides to more than 9000 nucleotides, while yeast TERRA has a more consistent length of approximately 400 nucleotides. The levels of TERRA transcribed are seemingly dependent on telomere length, with shorter telomeres promoting TERRA transcription and longer telomeres repressing expression (Iglesias *et al.*, 2011; Arnoult *et al.*, 2012). Shorter telomeres have fewer telomere-binding proteins that are responsible for transcriptional silencing of the telomere. TERRA appears to aid in telomerase recruitment and the increased levels of TERRA at short telomeres increase the rate of telomere extension at these eroded telomere ends (Cusanelli *et al.*, 2013). Additional functions for TERRA have been proposed, which include preventing separate telomeres from interacting and supporting chromosome end stability.

Telomerase

The telomerase enzyme solves the end-replication problem by extending the 3'-end of linear chromosomes to offset telomere shortening. In the mid-1980s, Carol Greider and Elizabeth Blackburn identified telomerase from *Tetrahymena thermophila*, an enzyme with the unique ability to add telomeric DNA repeats onto the 3'-end of DNA (Greider and Blackburn, 1985). Telomerase functions as a ribonucleoprotein enzyme that

Figure 3 The telomerase enzyme extends the G-strand of telomeric DNA. The Shelterin complex recruits telomerase selectively to the ends of shortened telomeres. Telomerase contains the template for telomeric DNA synthesis located within the integral TR (green) component for reiteratively catalyzing six nucleotide telomeric DNA repeats (red) to extend the G-strand. The mammalian CST complex recruits DNA pol α for C-strand in-fill (violet).

contains the catalytic telomerase reverse transcriptase (TERT) protein component and the integral telomerase RNA (TR) component that provides the template for DNA synthesis (Greider and Blackburn, 1987, 1989). With an internal template, telomerase adds single-stranded telomeric DNA repeats to the 3'-end of the G-strand, bypassing the requirement of a parental DNA template (Figure 3). The *de novo* addition of DNA repeats onto the chromosome 3'-end offsets DNA loss (Shippen-Lentz and Blackburn, 1990).

Telomerase synthesizes telomeric DNA during the late S-phase of the cell cycle. The mammalian Shelterin complex proteins POT1 and TPP1 actively recruit telomerase to the ends of critically short telomeres and stimulate telomerase DNA repeat addition (Xin *et al.*, 2007; Wang *et al.*, 2007). Telomerase binds to the 3'-end of the telomere G-strand overhang and catalyzes the addition of six nucleotides, GGTTAG in humans, which form the basic unit of a telomeric DNA repeat (Figure 3). Telomerase is processive, capable of adding hundreds of telomeric repeats in reiterative cycles of DNA synthesis. While telomerase specifically extends the G-strand overhang, C-strand in-fill requires a separate DNA synthesis mechanism. In vertebrates, following G-strand extension by telomerase, the CST complex binds to the single-stranded telomeric DNA and recruits DNA pol α to synthesize the complementary C-strand DNA using the G-strand as template (Wang *et al.*, 2012). The cell orchestrates a precise balance between recruitment of telomerase for G-strand extension, DNA pol α for C-strand in-fill, and exonucleases Apollo and Exo1 for generating the G-strand overhang (Wu *et al.*, 2012).

Telomerase Reverse Transcriptase

The TERT protein is the catalytic component of the telomerase enzyme. This protein is responsible for the synthesis of telomeric DNA repeats from the RNA template located within TR. The TERT protein component is present across all known taxa – with the exception of a subgroup of select insects – and is composed of four independently folded protein segments or domains. The four domains of TERT include the telomerase essential N-terminal (TEN) domain, the telomerase RNA binding domain (TRBD), the reverse transcriptase (RT) domain, and the C-terminal extension (CTE) domain (Figure 4). The central RT domain and the CTE domain contain motifs highly conserved in other RTs and DNA polymerases, while the TEN and TRBD domains are unique to the TERT protein (Lingner *et al.*, 1997).

The overall structure of the RT and CTE domains, like all known DNA polymerases, resembles a right hand with finger, palm, and thumb subdomains (Nakamura *et al.*, 1997; Gillis *et al.*, 2008). The 'fingers' in right handed DNA polymerases bind incoming nucleotides, while the 'palm' constitutes the catalytic site for nucleotide polymerization (Bosoy and Lue, 2001). Like that of all other DNA polymerases, within the palm of the TERT protein lie three invariant aspartic acids (Lingner *et al.*, 1997). This aspartic acid triad coordinates the positioning of two magnesium atoms. This acid-metal chemistry for nucleotide addition is common to all DNA polymerases. The TERT CTE domain has a similar overall structure to viral RTs 'thumb' domains, yet functions distinctly within the TERT protein (Gillis

Figure 4 The core telomerase enzyme is minimally composed of the TERT protein and TR component. The TERT protein is composed of four distinct functional domains: TEN (green), TRBD (blue), RT (red), and CTE (orange). The human TR is composed of three distinct functional domains: Pseudoknot (green), CR4/5 (blue), and H/ACA (violet). TEN and TRBD bind the similarly colored Pseudoknot and CR4/5 domains for formation of the telomerase RNP.

et al., 2008). The RT thumb domain positions the RNA template base-paired with a DNA primer, while the TERT CTE domain binds the 3'-end of the telomeric DNA to enhance DNA polymerization (Hossain *et al.*, 2002).

The TEN and TRBD domain contains TR binding sites critical for ribonucleoprotein assembly (Moriarty *et al.*, 2002; Bley *et al.*, 2011; Huang *et al.*, 2014). In addition, the TEN domain contains 'anchor' sites for binding single-stranded telomeric DNA (Sealey *et al.*, 2010). This DNA anchor site is important for delaying the complete dissociation of the telomerase enzyme from the telomeric DNA, enhancing the number of telomeric DNA repeats synthesized onto the end of the chromosome (Jacobs *et al.*, 2006).

Telomerase RNA

TR is the integral RNA component of the telomerase enzyme. In addition to providing the template for telomeric DNA synthesis, TR is essential for the formation of a functional telomerase ribonucleoprotein enzyme. The structure of TR is a remarkably divergent and complex, containing essential elements for defining the template region from the remainder of the RNA as well as specific regions necessary for TR biogenesis and telomerase assembly. TR from vertebrates and most fungi contains two universal structural domains: the pseudoknot domain and the Conserved Region 4 and 5 (CR4/5) domain (Chen *et al.*, 2002, 2000; Qi *et al.*, 2013; Figure 4). These two domains bind the TERT protein independently and are essential for telomerase activity (Tesmer *et al.*, 1999).

The TR template region is properly positioned within the TERT catalytic site by the pseudoknot domain (Zhang *et al.*, 2011). The pseudoknot domain contains the forenamed pseudoknot structure wherein the loop from a stem-loop base-pairs with a nearby single-stranded region (Figure 4). The TR pseudoknot structure includes a triple helix, a third RNA strand base-pairing with a canonically Watson-Crick base-paired RNA helix (Theimer *et al.*, 2005; Shefer *et al.*, 2007). Immediately

upstream of the 5'-end of the TR template lies the template boundary element which defines and safeguards the end of the template region (Chen and Greider, 2003). The template boundary element restricts access of the template adjacent RNA to the TERT catalytic site, preventing the use of this region as template by telomerase and synthesis of non-telomeric DNA.

The CR4/5 domain, termed three-way-junction in budding yeasts, is located at a distance downstream from the pseudoknot domain and is essential for telomerase assembly and activity (Chen *et al.*, 2002; Brown *et al.*, 2007; Figure 4). The high-affinity binding between the CR4/5 helical structure and the TRBD is specific and essential for telomerase to function (Bley *et al.*, 2011; Huang *et al.*, 2014). While the CR4/5 domain is conserved in vertebrates and the vast majority of fungal TRs, ciliate TRs contain a stem-loop IV that may be functionally analogous to the vertebrate CR4/5 domain (Robart *et al.*, 2010).

In vertebrate TR, a third domain called H/ACA domain located at the 3' distal region is necessary for TR biogenesis and localization to the correct nuclear compartment. The H/ACA domain, named for the similarity to H/ACA small nucleolar (sno) and small Cajal body (sca) RNAs, is composed of a tandem array of stem-loops with the forenamed boxes H and ACA intervening (Mitchell *et al.*, 1999; Jády *et al.*, 2004). In common with H/ACA snoRNAs and scaRNAs, the vertebrate TR H/ACA domain is bound by two copies of the dyskerin complex (Egan and Collins, 2010). The dyskerin complex is a tetrad of proteins comprising dyskerin, NOP10, NHP2, and GAR1 (Girard *et al.*, 1993; Maiorano *et al.*, 1999; Pogacíc *et al.*, 2000; Cheng and Roberts, 2001; Hamma *et al.*, 2005). Additionally, the 3'-most stem-loop in the human TR H/ACA domain is bound by telomerase Cajal body protein 1 (TCAB1) for localization to Cajal bodies, a nuclear compartment rich in RNA splicing and post-transcriptional modification machinery, prior to TR assembly with the TERT protein (Venteicher *et al.*, 2009).

The TR demonstrates astonishing divergence in length, sequence, and the folded RNA structure (Podlevsky *et al.*, 2008). Ciliates encompass the smallest and most compact TRs discovered to date, ranging from 147 to 205 nucleotides in length

(McCormick-Graham and Romero, 1995). In contrast, yeast and filamentous fungi have vastly larger TRs which range from 928 to 2425 nucleotides (Dandjinou *et al.*, 2004; Qi *et al.*, 2013). Vertebrate TRs are more modest in length, ranging from 312 to 559 nucleotides (Chen *et al.*, 2000; Xie *et al.*, 2008). The tremendous difference in TR length accommodates specific and distinct groups of TR binding proteins. While vertebrate TRs are bound by the dyskerin complex, yeast TRs are bound by Ever Shorter Telomeres 1 (EST1), the Ku heterodimer, and the Sm protein complex (Lendvay *et al.*, 1996; Peterson *et al.*, 2001), while ciliate TRs are bound by p50 and p65 proteins (Witkin and Collins, 2004; Min and Collins, 2009). Additionally, ciliate TRs are transcribed by RNA pol III and contain a terminal poly-U tract, while vertebrate and yeast TRs are transcribed by RNA pol II (McCormick-Graham and Romero, 1995; Mitchell *et al.*, 1999; Chapon *et al.*, 1997; Chen *et al.*, 2000). The different TR binding protein partners and even the RNA polymerase employed for transcription demonstrate the innate flexibility of TR biogenesis amongst distinct groups of species.

Syndromes of Short Telomeres

Telomere dysfunction leads to a myriad of human diseases and cellular ageing. Sufficient telomere length is essential for chromosome stability and permitting continuous cellular proliferation. Telomeres of insufficient length are unable to safeguard the ends of the chromosome from recognition by DNA damage repair, permitting chromosome fusions. Additionally, telomere length functions as a checkpoint for cell growth and division (d'Adda di Fagagna *et al.*, 2003). While the average length of telomeric DNA within humans is 10 000–15 000 base-pairs, as little as 1000 base-pairs is sufficient for chromosome end protection (Damm *et al.*, 2001). Since telomeres shorten with each cell division, the length of the telomere is a predictor of the number of cell divisions possible. This has earned telomeres the moniker 'mitotic clock,' since the telomeres countdown to senescence.

Numerous mutations within six of the genes that encode for the Shelterin complex and the telomerase holoenzyme are linked with telomere shortening and result in several human diseases. These syndromes of short telomeres include dyskeratosis congenita, aplastic anemia, and idiopathic pulmonary fibrosis (Armanios, 2009). Dyskeratosis congenita presents as a combination of skin and nail disorders, aplastic anemia as low peripheral blood cell counts, and idiopathic pulmonary fibrosis as the accumulation of fibrous material in the lungs (Fogarty *et al.*, 2003; Vulliamy *et al.*, 2006; Armanios *et al.*, 2007). Despite the different clinical presentations, all these diseases arise from the inability to maintain cell populations necessary for organ and tissue renewal. Telomeres shrink with human development and ageing; thus ageing itself can be considered a telomere-mediated disease (Harley *et al.*, 1990). Reciprocally, the vast majority of cancers appropriate telomerase for maintaining their continuous, deleterious growth (Kim *et al.*, 1994).

Alternative Lengthening of Telomeres

While telomerase is the prominent solution to the end-replication problem within eukaryotes and the vast majority of

cancers, there are telomerase-independent means of telomere length maintenance employed by specific cancers (Bryan *et al.*, 1995). These telomerase-independent pathways have been termed Alternative Lengthening of Telomeres (ALT). ALT employs telomere homologous recombination in which one telomere strand invades the other, using the other telomere as the template for elongation (Londoño-Vallejo *et al.*, 2004). Cells which employ ALT for telomere elongation have increased heterogeneity in telomere length and the presence of circular extra-chromosomal telomeric DNA repeats (Bryan *et al.*, 1997; Cesare and Griffith, 2004).

Flies from the dipteran insect lineage lack telomerase for telomere length maintenance (Biessmann and Mason, 1997; Pardue *et al.*, 1997). Specific *Drosophila* species telomeres are composed of tandem arrays of HeT-A and TART retrotransposons – parasitic genetic elements capable of self-replication through an RNA intermediate (Biessmann *et al.*, 1990). The appropriation of these retrotransposons is limited to only a select group of species even within the *Drosophila* genus. In most dipteran fly species, telomeres are instead composed of satellite sequences – repetitive DNA sequences of 50–800 base-pairs and employ a form of recombination similar to ALT for satellite sequence amplification for the extension and maintenance of these telomere lengths (Nielsen and Edström, 1993; Roth *et al.*, 1997; Biessmann *et al.*, 2000). The lack of telomerase within such a small and closely related group of species implies that telomerase was lost recently within this insect lineage.

The evolution of linear eukaryotic chromosomes set-in-motion the need for ancillary mechanisms to overcome the end-replication problem imposed by the limitations of conventional DNA polymerases. Additionally, a means of protection to delineate chromosome ends from damaged DNA was necessary. The solution was to cap the ends of chromosomes with a vast array of short telomeric DNA repeats bound by unique telomeric protein complexes, the Shelterin complex in humans. Telomere shortening following each cell division was virtually universally offset by the unique telomerase enzyme.

Glossary

ALT Alternative lengthening of telomeres, a recombination-based mechanism for lengthening telomeres independent of telomerase.

Breakage–fusion–bridge cycle A mechanism of chromosome instability induced by telomere loss; following replication, telomere-free sister chromatids fuse and are subsequently broken apart during anaphase, not necessarily at the site of fusion, creating new telomere-free ends which may continue the cycle.

End replication problem The progressive shortening of telomeres that occurs with each cell division as a consequence of the mechanism of lagging strand DNA synthesis and telomere resection.

G-quadruplex A secondary structure possible in certain G-rich sequences, whereby four single-stranded portions of DNA or RNA form a helical structure stabilized by cyclic hydrogen bonding between guanine bases.

Senescence A state of irreversible cell cycle arrest induced by either telomere shortening (replicative senescence) or stress (stress-induced premature senescence).

Shelterin A six-member telomere-specific protein complex consisting of TRF1, TRF2, POT1, Rap1, TPP1, and TIN2; shelterin is involved in regulating numerous processes occurring at the telomere.

Telomerase A ribonucleoprotein holoenzyme that adds telomeric DNA repeats to the terminal end of an existing telomere, minimally composed of the telomerase reverse transcriptase protein (TERT) and the telomerase RNA component (TERC or TR).

Telomere crisis A state of excessive telomere shortening occurring in p53-deficient cells; critically short telomeres fuse to one another, initiating the breakage–fusion–bridge cycle and causing substantial genomic instability.

TERRA Telomeric repeat-containing RNA, the functional RNA product resulting from RNA polymerase II transcription of telomeres.

t-Loop A secondary structure that forms at telomeres; strand invasion of the 3' ssDNA telomere overhang into telomeric dsDNA (of the same telomere) producing a dsDNA loop (the t-loop) and a small ssDNA displacement loop (D-loop) at the site of invasion.

Introduction

All eukaryotic genomes are organized into linear chromosomes. As a result, each chromosome possesses termini that must be protected from two distinct problems not present in organisms with circular genomes. The first of these is the end replication problem, a consequence of the mechanism of lagging strand DNA synthesis. During lagging strand synthesis, when the last Okazaki fragment on the lagging strand template is processed to remove the ribonucleotide primer, an irreparable 5' gap remains. This gap on the lagging strand, as well as nucleolytic processing of the chromosome ends, results in a progressive shortening of the linear chromosome with each cell division (Zakian, 2012). Telomeres are the means by which cells avoid the loss of genetic information that would occur as a result of the end replication problem – instead of a progressive loss of protein-coding sequences, a progressive loss of noncoding telomere sequence occurs instead. In serving as a stopgap to the end replication problem, telomeres also act as a molecular clock that regulates cellular lifespan. In the absence of elongation mechanisms, telomeres eventually erode to lengths that are no longer sufficient to protect against loss of genetic information. Once telomeres become critically short, they trigger cellular senescence to prevent continued division that might result in a loss of genetic information and genome instability (Frias *et al.*, 2012). The second potential problem resulting from linear chromosome ends arises from the fact that all cells possess exquisitely sensitive mechanisms to recognize free DNA ends as DNA damage. By

coordinating the activities of DNA repair proteins, telomeres protect natural chromosome ends from DNA repair events that would result in chromosome fusions (de Lange, 2004). Since inappropriate chromosome fusions lead to genome instability, telomere integrity is essential for cell proliferation (Frias *et al.*, 2012).

The molecular events that telomeres are associated with have consequences reaching far beyond the proliferation of a given cell. Telomere dysfunction has been linked to a number of diseases including dyskeratosis congenita (DC), aplastic anemia, and emphysema (Armanios and Blackburn, 2012). Despite the wide range of organismal effects that can occur as a result of telomere dysfunction, perhaps no disease is more strongly linked to telomere biology than cancer. Telomere attrition is classically considered to be a tumor-suppressive mechanism due to the fact that shortened telomeres cause checkpoint activation and cellular senescence (Xu *et al.*, 2013). Because senescence is a potent obstacle to transformation, cells that become neoplastic must stabilize their telomeres. Along similar lines, telomere shortening or loss has the potential to cause substantial genome instability resulting in apoptosis or mitotic catastrophe (Xu *et al.*, 2013). Despite these strong tumor-suppressive effects, telomere dysfunction can also act as a tumor promoting mechanism. Since genome instability can lead to oncogenic translocations, gene amplification, and loss of heterozygosity of tumor suppressor genes, telomere dysfunction can also enhance the transformation process (Xu *et al.*, 2013). These opposing roles – preventing and promoting cancer – underscore the complexity of the molecular activities

that maintain telomeres, and the activities that take place in response to telomere shortening.

Telomere Structure and Proteins

Telomere DNA

The telomere sequence in eukaryotic organisms is canonically composed of short, G-rich repeats. Indeed, all identified vertebrate telomeres are composed of the sequence 5'-(TTAGGG)_n-3' oriented toward the chromosome terminus (McEachern *et al.*, 2000). Similar highly repetitive, G-rich sequences exist in other organisms; for instance, *Tetrahymena thermophila* telomeres consist of 5'-(TTGGGG)_n-3' repeats (Fulcher *et al.*, 2014). Telomeres are composed largely of double-stranded DNA (dsDNA), with a relatively short 3' single strand DNA (ssDNA) overhang of the G-rich strand (Sfeir, 2012). The length of the overhang can vary – in humans it is typically between 30 and 500 nucleotides – but its presence is essential, as evidenced by the fact that it is actively produced by resection following DNA replication (Novo and Londoño-Vallejo, 2013; Sfeir, 2012). Telomeres span a wide range of total lengths, from as short as 300 base pairs in yeasts, to between 2 and 15 kb in humans, and as long as 150 kb in tobacco (Fulcher *et al.*, 2014).

Not all organisms follow the theme of compact, regular repeats; for instance, *Saccharomyces cerevisiae* telomeres are usually designated 5'-(C₁₋₃A/TG₁₋₃)-3' to indicate a consensus core telomere sequence (Wellinger and Zakian, 2012). Budding yeast telomere repeats in fact range from 8 to 26 bp in length, and are on average less G-rich than typical telomere repeats (McEachern *et al.*, 2000). Even human telomeres show slight variability, generally having perfect repeats in the centromere-distal majority of the telomere with variant repeats occurring in the centromere-proximal end of the telomere (McEachern *et al.*, 2000). Small variations like those found in human telomeres are likely the consequence of errors by the DNA replication machinery. Since the centromere-proximal end of the telomere is more likely exclusively produced by the DNA replication machinery rather than telomerase, sequence polymorphisms can manifest and remain (McEachern *et al.*, 2000).

Telomere Secondary Structure

Because of the repetitive sequence and ssDNA overhang, telomeres can form secondary structures more complex than a linear dsDNA stretch with an ssDNA terminus. The most documented of these is the telomeric loop, or t-loop. T-loops form by a strand invasion event in which the 3' ssDNA overhang invades the dsDNA portion of the telomere. This event produces a small (approximately 150 nucleotide) ssDNA displacement loop (D-loop) of G-rich sequence at the site of invasion, as well as a large dsDNA loop (t-loop) (de Lange, 2004). T-loops were first identified in electron micrographs of telomeric DNA, and have since been observed using super-resolution fluorescence microscopy (de Lange, 2004; Doksan *et al.*, 2013). At face value, t-loops would seem to be an effective means to prevent end-to-end chromosome fusions;

by sequestering the 3' overhang, t-loops inhibit ATM signaling and nonhomologous end joining. However, t-loops themselves resemble strand invasion intermediate structures produced during homologous recombination; it is unclear if such a structure elicits a DNA damage response (DDR) if persistent, and how telomeres might avoid this response. It is likely that telomeric proteins play a role in both the formation and stabilization of t-loops; the telomere protein TRF2 in particular is sufficient for t-loop formation *in vitro*, and is necessary for t-loop formation and maintenance in mammalian cells (de Lange, 2004; Doksan *et al.*, 2013).

In addition to t-loops, telomeres are also capable of forming G-quadruplexes. G-quadruplexes form by an association of four single strands of DNA or RNA (monomeric, dimeric, or tetrameric in origin) in a helical structure, where the strands assemble such that four guanines align in a cyclic Hoogsteen hydrogen-bonded tetrad (Paeschke *et al.*, 2010). G-quadruplexes are characterized by the stacking of multiple tetrad cores that are connected by linker 'loops,' and can form in multiple orientations (Phan, 2010). Both the ssDNA overhang and ssDNA portions of the G-strand that form during replication or repair can presumably form into G-quadruplexes. The ability of the telomere to form G-quadruplexes is a significant phenomenon, as G-quadruplexes inhibit both semiconservative DNA replication and telomerase-mediated telomere lengthening (Paeschke *et al.*, 2011). Data from ciliates demonstrating that G-quadruplexes form at telomeres in a cell cycle-specific manner, and the observation that treatment of mammalian cells with G-quadruplex-stabilizing small molecules triggers telomere dysfunction, suggest that G-quadruplexes at the telomere must be actively regulated by the cell (Lipps and Rhodes, 2009). Among the strongest candidates for G-quadruplex regulation in the cell are helicases; in particular, the Fanconi anemia group helicase FANCD1 and RecQ helicase BLM are known to unwind G-quadruplexes, and are known to contribute to telomere stability (Lipps and Rhodes, 2009).

Proteins Associated with the Telomere

In addition to the DNA itself, telomeres are host to a number of proteins important for telomere maintenance and function. In mammals, the network of proteins present at the telomere are coordinated by six telomere-specific proteins: TRF1 (telomeric repeat-binding factor 1, also TERF2), TRF2 (telomeric repeat-binding factor 2, also TERF2), POT1 (protection of telomeres protein 1), Rap1 (telomeric repeat-binding factor 2-interacting protein 1, also TERF2IP), TPP1 (adrenocortical dysplasia protein homolog, also ACD), and TIN2 (TRF1-interacting factor 2, also TIN2) (de Lange, 2005). These six proteins together form the shelterin complex, which exclusively binds telomeres due to the DNA-binding specificities of TRF1 and TRF2 for telomeric dsDNA, and of POT1 for telomeric ssDNA.

TRF1 and TRF2 share homology in the form of a central TRFH dimerization domain and C-terminal Myb DNA-binding domain, though TRF1 possesses an acidic N-terminus, while TRF2's N-terminus is basic. TRF1 is also substantially more divergent (65% identity between human and mouse) in

mammalian evolution than TRF2 (82% identity) (Broccoli *et al.*, 1997). While both proteins bind telomeric dsDNA and are abundant at telomeres, their functions in telomere maintenance and stability are very different. TRF1 is required for semiconservative DNA replication through the telomere, and prevents a phenotype known as telomere fragility by recruiting helicases to the telomere to facilitate replication fork progression (Sfeir, 2012). TRF1 is also capable of looping, bending, and pairing arrays of telomere repeats, which may be involved in positioning or folding of telomeres, though TRF1 is dispensable for t-loop formation (de Lange, 2005; Doksan *et al.*, 2013). TRF2 suppresses ATM kinase activation at the telomere, thus preventing a DDR (H2AX phosphorylation and 53BP1 accumulation) and p53 activation (Sfeir, 2012). In the absence of TRF2, ligase IV- and Ku-mediated nonhomologous end joining occurs, resulting in aberrant end-to-end chromosome fusions and early embryonic lethality in mice. The protective activities of TRF2 likely originate from its ability to facilitate t-loop formation, as well as its role (along with TRF1) in recruiting TPP1 to the telomere (de Lange, 2005, 2004; Doksan *et al.*, 2013). Putative TRF1/2 homologs have been identified in *Schizosaccharomyces pombe*, trypanosomes, and plants (Sfeir, 2012).

The other mammalian shelterin protein with telomere sequence binding specificity, POT1, binds to the ssDNA overhang. POT1 is responsible for suppression of ATR kinase activation at the telomere, which is achieved by exclusion of the ssDNA-binding protein RPA from the ssDNA overhang (Baumann and Price, 2010). POT1 also restricts the length of the ssDNA overhang and regulates the activity of telomerase by competing for binding at the overhang, which is the substrate for telomerase elongation (Longhese *et al.*, 2012; Sfeir, 2012). POT1 is largely conserved among eukaryotes, with homologs in *S. pombe*, *Tetrahymena*, nematodes, and plants (Baumann and Price, 2010). In mouse and *Tetrahymena*, there are two POT1 gene homologs, *Pot1a* and *Pot1b*, with each playing a subset of the roles attributed to the single POT1 gene observed in human and yeast.

The three other shelterin proteins (Rap1, TPP1, and TIN2) lack the ability to bind telomeric sequence directly in vertebrates, but are telomere-specific by virtue of their direct or indirect binding to TRF1 and TRF2. Indeed, simultaneous deletion of TRF1 and TRF2 from cells results in telomeres completely devoid of shelterin (Sfeir and de Lange, 2012). Rap1 is the most conserved of all the shelterin proteins and the only shelterin protein with well-defined extra-telomeric functions – it is a transcriptional regulator and can modulate nuclear factor kappa B (NF- κ B) signaling. At the mammalian telomere, Rap1 is a negative regulator of telomere length. It also acts with POT1 to repress aberrant homology-directed repair through an unclear mechanism (Sfeir, 2012). In *S. cerevisiae*, which lacks a TRF1/2 homolog, Rap1 is highly diverged from its orthologs and directly binds telomeric dsDNA; it effectively serves as the shelterin core in this yeast (de Lange, 2005). TIN2 is a 'bridging' protein that connects TRF1 and TRF2 to one another, and recruits TPP1 to the telomere. TPP1 in turn is required for efficient recruitment of POT1 to the telomere, as POT1's DNA-binding affinity is insufficient to keep it tethered to the ssDNA overhang (Sfeir, 2012). Both TIN2 and TPP1 are exclusive to vertebrate telomeres, and their

emergence may coincide with the appearance of two TRF genes (de Lange, 2005; Figure 1).

In addition to the telomere-specific shelterin proteins, a growing number of other proteins localize to telomeres and are important for telomere function. The majority of these proteins are associated with DNA metabolism. The protein complex CST, consisting of Cdc13, Stn1, and Ten1 in *S. cerevisiae* and CTC1, STN1, and TEN1 in mammals, associates with the ssDNA telomere overhang and due to structural similarity to the heterotrimeric RPA complex has been proposed to function as a 'telomere-specific RPA' (Longhese *et al.*, 2012). The RecQ helicases WRN and BLM interact with shelterin and play roles in lagging strand telomere synthesis and replication fork progression (de Lange, 2005). These are but a few of the numerous proteins that localize to the telomere and contribute to telomere synthesis and maintenance.

Telomere Replication and Length Maintenance

Telomeres, like the rest of the genome, must be replicated during S phase to ensure genome continuity during cell division. Telomeres can be replicated primarily in two ways: first, the semiconservative DNA replication machinery replicates telomeres along with the rest of the genome, and second, the ribonucleoprotein (RNP) enzyme telomerase adds telomere repeats to extend telomeres. In addition to these two main mechanisms for telomere replication and maintenance, there are two additional identified means of telomere length maintenance: recombination-based telomere maintenance and the alternative lengthening of telomeres (ALT) mechanism. Lastly, some insects maintain their telomeres by a unique mechanism involving retrotransposition, but this will not be discussed here (de Lange, 2004).

Semiconservative Telomere Replication

Telomere replication poses unique challenges for the semiconservative DNA replication machinery. The first of these challenges is the consequence of the telomere's location at chromosome termini. Unlike the rest of the genome, which can be replicated by one or more DNA replication origins with replication forks approaching from either direction, the most centromere-distal origin is thought to be the sole origin responsible for the replication of a given telomere. Additionally, because there are no known replication origins within the telomere, the 'last' origin to fire must replicate the entire length of the telomere; in the event of fork collapse, telomere replication may remain incomplete (Gilson and Géli, 2007). This potential problem is exacerbated by the second main challenge in telomere replication: the repetitive, G-rich sequence, which leads to increased replication fork stalling compared to the rest of the genome (Cesare and Karlseder, 2012). The secondary structures that telomeric DNA forms, in particular G-quadruplexes and t-loops, must be resolved into linear dsDNA for replication to occur.

The combination of structures that induce replication fork stalling and the lack of a replication fork approaching from the opposite direction to rescue a stalled fork necessitates robust

Figure 1 A diagrammatic representation of telomere structure and telomere-binding proteins. TRF1 (green) and TRF2 (red) form homodimers and directly bind telomere dsDNA. TIN2 (blue) acts as a bridge between the homodimers and interacts with TPP1 (yellow). TPP1 also interacts with POT1 (orange), which binds telomere ssDNA at the 3' overhang. Below, the t-loop structure is shown, where the G-rich 3' end loops and hybridizes with the C-rich strand, forming a displacement loop.

mechanisms to ensure that telomere replication is completed. These mechanisms are coordinated by the shelterin complex, which recruits DNA replication and repair proteins to the telomere. In *S. pombe*, the TRF1/2 homolog Taz1 prevents replication fork arrest and telomere loss in a telomerase-negative background (Gilson and Géli, 2007). Subsequent work in murine cells has shown that TRF1 is required to facilitate replication fork progression through the telomere and prevent telomere fragility, and that this activity depends upon the helicases BLM and RTEL1 (Sfeir *et al.*, 2009). TRF2 also plays critical roles in telomere replication – both by recruiting the RecQ helicases BLM and WRN to the telomere, and by acting in a pathway with Apollo and topoisomerase 2 α to relieve topological stress during replication (Ye *et al.*, 2010). The recruitment of two RecQ helicases, BLM and WRN, by shelterin is not coincidental; both proteins are able to unwind G-quadruplexes and are theorized to have overlapping functions in resolving G-quadruplexes formed on the lagging strand during replication.

The cooperation between shelterin and its binding partners described above ensures that replication forks can progress through the telomere with as little stalling as possible. Nevertheless, replication forks do stall in telomeric sequence, and additional mechanisms are in place to ensure successful fork restart. The DNA replication and repair protein flap endonuclease 1 (FEN1) localizes to telomeres during and after replication, and ensures that replication forks are reinitiated on the lagging strand template following stalling (Saharia *et al.*, 2010). The mammalian CST complex rescues stalled replication forks that occur as a result of replication stress by facilitating dormant origin firing (Stewart *et al.*, 2012). Stalled replication forks at the telomere appear to require ATR, which is recruited to telomeres during S phase, for restart (Verdun and Karlseder, 2006). These are unlikely to be the only contributing mechanisms for replication fork restart at the telomere. The preponderance of DNA replication and repair proteins that are recruited to the telomere to facilitate replication fork progression and fork restart following stalling

illustrates the difficulty of telomere replication by the semi-conservative DNA replication machinery, as well as the robust series of mechanisms in place to ensure that replication is completed in spite of the challenges.

The fact that both leading and lagging strand-replicated telomeres possess similar 3' ssDNA overhangs implies that at least the leading strand, which would be expected to produce a blunt end, has to be processed to produce an overhang. In fact, leading and lagging strand-replicated telomere ends are significantly resected and processed following the completion of semiconservative DNA replication (Gilson and Géli, 2007). This process must be highly regulated by the cell, as too little resection would generate a short overhang which precludes POT1 binding and t-loop formation, while too much resection would accelerate the end replication problem. In *S. cerevisiae*, resection of the leading strand-replicated telomere to produce the G-rich overhang is facilitated by the same DNA repair proteins involved in 5' resection at DNA double strand breaks prior to homologous recombination, notably Cdk1 and the Mre11–Rad50–Xrs2 (MRX) complex. Indeed, yeast strains with deficient Mre11 exhibit shorter 3' ssDNA overhangs (Gilson and Géli, 2007). Following recognition of the end by MRX, the nucleases Exo1 and/or Dna2 are recruited to the 5' end, and in concert with the helicase Sgs1, cleave the 5' end to produce the 3' ssDNA overhang (Stewart *et al.*, 2012). In mammalian cells, the Apollo nuclease is recruited to telomere ends by its interaction with TRF2. At the leading strand-replicated telomere, Apollo initiates resection of the 5' end. At the lagging strand-replicated telomere, where an overhang already exists following replication, POT1b binds the ssDNA and inhibits the resection activity of Apollo; similarly, after a sufficient ssDNA overhang is generated at the leading strand-replicated telomere, POT1b binds and inhibits further resection by Apollo (Wu *et al.*, 2012). Exo1 then further and transiently resects the 5' ends at both strands to produce long overhangs. Lastly, POT1b recruits CST and polymerase α to shorten the extended overhangs, presumably by fill-in C-strand synthesis (Wu *et al.*, 2012).

Telomerase

Semiconservative replication and telomere end processing cause the end replication problem, which manifests as progressive telomere shortening with each cell division cycle. The solution to the end replication problem is telomerase, a holoenzyme minimally composed of the telomerase reverse transcriptase protein (TERT) and the telomerase RNA component (TERC or TR). TERC binds accessory proteins in addition to TERT, which contribute to telomerase localization and processing (Martínez and Blasco, 2011). Telomerase adds telomeric DNA repeats to the terminal end of an existing telomere, thus lengthening telomeres and offsetting the end replication problem.

Telomerase is unique among known reverse transcriptase enzymes in being an RNP. The TERT protein is the catalytic portion of the holoenzyme, and consists of four conserved structural domains. Two of these, the reverse transcriptase and C-terminal extension domains, are conserved between TERT and other reverse transcriptases; the telomerase essential N-terminal domain and telomerase RNA-binding domain are

unique to TERT (Podlevsky and Chen, 2012). The RNA portion of the telomerase RNP, TERC, is required for telomerase activity not only because it provides the telomere repeat sequence template, but also because two conserved regions, the template/pseudoknot domain and the CR4/5 domain, contribute to template positioning in the active site and provide important protein–nucleic acid contacts (Podlevsky and Chen, 2012). In addition to these two regions, which are conserved among all known species, vertebrate TERCs contain a conserved H/ACA domain. Each of two stems in the H/ACA domain binds a protein complex consisting of dyskerin, NOP10, NHP2, and GAR1. These proteins are required for TERC maturation and processing, RNP biogenesis, and Cajal body localization of TERC (Podlevsky and Chen, 2012).

TERT protein production occurs via the canonical processes of mRNA transcription and cytoplasmic translation, after which TERT is first recruited to nucleoli, and then Cajal bodies. TERC is transcribed by RNA polymerase II, after which the ends are processed; TERC binds the dyskerin-anchored complex of accessory proteins, which facilitate maturation and localization to Cajal bodies. The chaperone proteins HSP90 and p23 facilitate the assembly of the TERC–accessory protein complex with TERT into the active telomerase RNP holoenzyme, after which it localizes to telomeres (Podlevsky and Chen, 2012).

At the telomere, the catalytic process of telomere elongation occurs in two steps. In the first step, the 3' end of the telomere base pairs with the 5' region of TERC; the TERT active site then uses the 3' end of the telomere as a primer to reverse transcribe a telomere repeat (in human, the six nucleotides 5'-GGTTAG-3') using TERC as a template. In the second step, TERC dissociates from the telomeric DNA, translocates 5'-to-3' along the DNA, and re-anneals for a new round of nucleotide addition (Podlevsky and Chen, 2012). By repeating the synthesis and translocation steps, telomerase can processively add repeats to a single telomere end without ever completely dissociating from the DNA. Here, shelterin plays a role in telomere synthesis, as the POT1–TPP1 complex has been shown to hold the telomeric DNA primer close to telomerase, inhibiting primer release and enhancing processivity (Podlevsky and Chen, 2012). Telomerase activity is also restricted in a shelterin-dependent manner; POT1 bound to the ssDNA overhang is thought to limit the initial binding of telomerase to the telomere, and the t-loop structure prevents telomerase activity (de Lange, 2005). Once telomerase dissociates from its template, polymerase α synthesizes the complementary C-rich strand. It is thought that the CST complex, which is known to interact with the polymerase α complex, facilitates this event (Gilson and Géli, 2007). In yeast, telomere repeat-containing RNA (TERRA), the noncoding RNA product of telomere transcription, may act as a seed to nucleate clusters of telomerase prior to telomere recruitment; TERRA transcription is induced by telomere shortening (Cusanelli *et al.*, 2013).

Recombination at Telomeres and ALT

In addition to lengthening by telomerase activity, cells have evolved other mechanisms to elongate or maintain telomeres. In *S. cerevisiae*, deletion of the telomerase reverse transcriptase

EST1 produces colonies of survivor cells. Genetic analysis revealed the requirement for recombination in virtually all *est1Δ* survivor cells, as *est1Δ rad52Δ* strains produce virtually no survivors (Wellinger and Zakian, 2012). In addition to *RAD52*, all survivor cells require the Pol32p replication protein. Survivors are categorized into one of two types (I and II), which appear to have different mechanisms but are not mutually exclusive. Type I survivors have telomeres with multiple, repeated Y' subtelomere elements and short, terminal telomere repeats; they also possess extrachromosomal circular Y' elements thought to serve as recombination substrates. These cells grow relatively slowly, easily convert to type II survivors, and require *RAD51*, *RAD54*, and *RAD57* in addition to *RAD52* and *POL32* (Wellinger and Zakian, 2012). Type II survivors have telomeres with few subtelomere repeats but extensive amplification in telomere repeats. The telomeres in these cells may depend on rolling circle amplification as an initiating event to lengthen their telomeres. Type II survivors require *MRX*, *RAD59*, and *SGS1* (Wellinger and Zakian, 2012). Interestingly, the recombination-mediated mechanisms of telomere maintenance in yeast appear to be promoted by RNA:DNA hybrid formation between telomeric DNA and TERRA (Balk *et al.*, 2013). This observation suggests that TERRA may be required for both telomerase-mediated and recombination-mediated telomere elongation pathways.

In mammalian cells lacking telomerase activity, the ALT mechanism provides a means to maintain telomere length. Found in 10–15% of human cancers, ALT appears to be recombination-based and is characterized by several striking phenotypes. ALT cells possess an abundance of extrachromosomal telomeric DNA, much of which is in the form of double-stranded telomeric circles (t-circles) and C-rich single-stranded telomeric circles (C-circles) (Cesare and Reddel, 2010). ALT cells also exhibit telomere localization to promyelocytic leukemia (PML) nuclear bodies, elevated levels of telomere sister chromatid exchange (T-SCE) events, and heterogeneous chromosomal telomere lengths. The molecular mechanism(s) responsible for ALT have remained elusive, and two models have emerged to explain it. First, the unequal T-SCE model proposes that T-SCE events produce long and short telomere lengths in the chromosomes experiencing T-SCE; if the chromosomes with longer telomeres were able to segregate into one of the two daughter cells, the enhanced proliferative capacity of one daughter over the other could produce selection at the population level for theoretically unlimited proliferation (Cesare and Reddel, 2010). The second model, which is not mutually exclusive from the unequal T-SCE model, proposes that ALT is the result of homologous recombination-dependent DNA replication. In this model, shorter telomeres extend by recombination-based DNA synthesis using an existing telomere sequence substrate in the cell. The telomere substrate for the elongating telomere could be a telomere on another chromosome, the same telomere via t-loop formation, linear extrachromosomal telomeric DNA, t-circles, and/or C-circles (Cesare and Reddel, 2010). Both telomere elongation and length maintenance in ALT cells appear to depend on a striking number of DNA replication and repair proteins, which suggests that ALT results from deregulation of normal DNA metabolic processes. Indeed, the shelterin proteins TRF2 and POT1 have been suggested as

suppressors of ALT due to both proteins' ability to inhibit recombination at the telomere; ALT cells' vast expansion of telomeric DNA content may dilute shelterin saturation at telomeres and contribute to the phenotype (Cesare and Reddel, 2010). Like in recombination-mediated telomere elongation in yeast, TERRA may play a role in ALT. Recent data suggests that RNA:DNA hybrid levels between TERRA and the telomere are 'fine-tuned' by RNase H1 expression in ALT cells (Arora *et al.*, 2014).

Telomere Physiology

Senescence and Telomere Crisis

One of the most significant consequences of telomere erosion at the cell biological level is the induction of cellular senescence. Indeed, the fact that telomere length is the primary determinant of cellular lifespan is well established (Deng *et al.*, 2008). Telomere shortening beyond a critical length causes deprotection of the telomere via a loss of TRF2. Deprotection induced by replicative shortening or other telomere dysfunction induces a DDR. The DDR induced by telomere dysfunction causes phosphorylation of H2AX and recruitment of 53BP1 and other DNA repair proteins to the telomere. Like the classical DDR, the DDR induced by telomere attrition activates both the ATM and ATR checkpoints, which in turn activate p53 via the CHK1 and CHK2 kinases (Deng *et al.*, 2008). p53 activation by telomere shortening induces one of two physiological consequences: either entry into cellular senescence by p21 and RB signaling, or apoptosis (Frias *et al.*, 2012). Both senescence and apoptosis serve as potent antiproliferative mechanisms in cells with eroded telomeres (Figure 2).

Absence of a functional p53 and Rb checkpoint, as often occurs in cancer cells, abrogates both senescence and apoptosis as responses to telomere dysfunction and attrition. Because this causes checkpoint bypass and continued proliferation, telomeres in p53-deficient cells will continue to shorten, ultimately reaching a condition called crisis. Crisis inherently acts as a second checkpoint to continued proliferation; critically short telomeres induce aberrant end-to-end fusions between chromosomes followed by chromosome breakage and additional fusion events in what is referred to as the breakage–fusion–bridge cycle (Deng *et al.*, 2008). The breakage–fusion–bridge cycle causes massive genomic instability and aneuploidy, both of which lead to rapid cell death in a majority of cells. However, a small fraction of cells are able to escape crisis by activating either telomerase or the ALT pathway; in these cells, the chromosome fusions resulting from crisis can produce oncogene amplification, tumor suppressor loss of function, and gene fusions that contribute to rapid proliferation and tumorigenesis (Deng *et al.*, 2008).

Telomeres in Cancer Cells

Telomere biology contributes to cancer phenotypes via two distinct but related mechanisms. First, telomere shortening induces senescence and/or apoptosis, acting as a significant antiproliferative barrier to the incipient tumor cell; these cells must

Figure 2 A depiction of telomere length over the course of cell divisions. Germline cells and embryonic stem cells (green) possess high telomerase activity and maintain long telomeres. Adult stem cells and multipotent progenitor cells (purple) possess detectable telomerase activity, but do not express telomerase sufficiently to entirely prevent telomere shortening; the telomeres in these cells shorten gradually over time. Somatic cells have no detectable telomerase activity, and the telomeres in these cells shorten with each cell division. When telomeres shorten to a particular length (M1), most cells enter senescence and cease dividing. In cells without functional p53/Rb checkpoints, senescence is bypassed; cell division and telomere shortening continue until telomere length becomes short enough to trigger crisis (M2). The majority of cells that reach crisis die; however, a very small subset of incipient cancer cells that reach crisis activate either telomerase or the ALT pathway to stabilize their short telomeres, thus becoming immortal.

activate either telomerase or ALT to continue proliferating. Second, telomere dysfunction, whether induced by DNA damage, genetic mutation, or avoidance of replicative senescence causes genomic instability that can drive tumorigenesis.

The observation that telomerase is aberrantly activated in as many as 85–90% human cancers, with ALT mechanisms active in the remainder, demonstrates the absolute barrier that telomere shortening imposes on incipient tumor cells' ability to survive (Gomez *et al.*, 2012). Despite the universal requirement for a telomere maintenance mechanism for unlimited proliferation, the significance of a tumor cell's use of telomerase versus ALT remains unclear. Several studies have identified an ability of cells to switch between the two mechanisms; of particular note is the ability of telomerase-positive cancer cells to become ALT-positive upon genetic or pharmacologic inactivation of telomerase (Hu *et al.*, 2012; Queisser *et al.*, 2013). In tumors that are telomerase-positive, studies conflict on the relevance of telomerase expression levels or activity as a prognostic marker. In some late-stage non-small cell lung cancers, colorectal cancers, and soft tissue sarcomas, telomerase expression correlates with poor prognosis, but many of these studies remain controversial (Chen and Chen, 2011). Tumors that are ALT-positive (commonly, glioblastoma multiforme and sarcomas) frequently have poor prognosis (Cesare and Reddel, 2010).

While aberrant telomere elongation by telomerase or ALT contributes directly to the proliferative capacity of cancer cells, telomere-related genomic instability is perhaps just as significant a contributor to tumorigenesis. As described in the Senescence and Telomere Crisis section, the breakage–fusion–

bridge cycle can arise from critically short or lost telomeres. In cancer cells, critically short telomeres are likely to induce the breakage–fusion–bridge cycle, resulting in genomic instability and generating tumor-promoting conditions. Indeed, mice with a *TERC* deletion and p53 deletion experience a wide range of carcinomas consistent with human cancers; when examined for cytogenetic abnormalities, the tumor cells in these mice show chromosome rearrangements with inverted repeats that are consistent with the breakage–fusion–bridge model (Murnane, 2010). Human cancer cells frequently contain amplified regions in the genome with inverted repeats (Murnane, 2012). Analysis of tumor samples by chromosome painting indicates that the breakage–fusion–bridge cycle frequently involves a single chromosome involved in multiple sister chromatid fusions, continuing over multiple generations until telomere stability can be achieved; this allows the cell to survive and facilitates substantial amplification of loci on the involved chromosome(s) (Murnane, 2012). In addition to amplification events generated by the breakage–fusion–bridge cycle, telomere loss can trigger end-to-end chromosome fusions that ultimately produce gross chromosomal rearrangements. These rearrangements are capable of producing fusion genes that encode oncogenic proteins in specific human cancers (Jones *et al.*, 2012).

Noncancer Telomere-Related Diseases

Diseases with telomeric origin or contribution can largely be grouped into two categories: those that are caused by mutation to specific genes with telomeric functions and those that are associated with changes in telomere length. The first category, often referred to as telomeropathies or telomere syndromes, constitutes a diverse group of diseases that are monogenic in origin, with mutations typically occurring in one of several telomere-associated genes. The most well-known telomeropathy is DC, a disease initially presenting with nail dystrophy, leukoplakia, and abnormal skin pigmentation; DC patients frequently progress to experience aplastic anemia and increased cancer incidence (Savage and Bertuch, 2010). Among the most frequently mutated genes in DC are *TERC* and *TERT*; DC is also associated with mutations in *DKC1* (common), *TINF2* (common), *NHP2* (rare), and *NOP10* (rare) (Holohan *et al.*, 2014). In addition, three other disorders presenting with overlapping symptoms – Hoyerall-Hreidarsson, Revesz, and Coats plus syndromes – are associated with mutations in the same group of genes, and may constitute a group of diseases including DC with common origins that exhibit distinct phenotypes due to different mutations or penetrance (Armanios and Blackburn, 2012). Most of the mutations identified in DC and the DC-related syndromes cause decreased telomerase function; in affected cells, telomere length is frequently below the first percentile in the population for the age of the patient (Savage and Bertuch, 2010). Mutations in *TERC* and *TERT* have also been identified in studies as contributors to aplastic anemia, idiopathic pulmonary fibrosis, and unexplained severe liver disease (Savage and Bertuch, 2010). The symptoms of these conditions are all observed in DC patients as either complications or comorbidities, suggesting that abrogation of telomerase function by mutation of *TERC*, *TERT*, or another protein can produce a wide spectrum of disease presentations that are all caused by similar molecular mechanisms.

Two mutated genes identified in diseases of the DC spectrum, *TINF2* (common) and *CTC1* (rare), produce proteins not known to directly affect telomerase function. *TINF2*, a shelterin complex member, could indirectly affect telomerase recruitment by modulating the binding of other shelterin proteins to the telomere, but the mechanism remains unclear. *CTC1*, associated only with Coats plus syndrome, is a member of the mammalian CST complex and thus facilitates telomere replication, but there is little evidence about how it might contribute to the disease (Armanios and Blackburn, 2012).

In addition to the monogenic telomeropathies described above, several age-related human diseases show association with telomere length. A wide number of risk factors for atherosclerosis (smoking, hypertension, and obesity), as well as atherosclerosis itself, have been studied with regard to telomere length. Reports indicate that tobacco use, hypertension with sclerotic plaques, and weight gain correlate with shorter telomere lengths; multiple studies have demonstrated that shorter telomeres or increased telomere attrition are present in atherosclerotic patients (Khan *et al.*, 2012). Some of these studies, particularly those examining atherosclerosis risk factors as opposed to the disease itself, have weaknesses: several studies were unable to control all the confounding factors, while others showed statistically significant effects only in certain subgroups (i.e., males or females). Nonetheless, the overall picture of data certainly indicates that shorter telomere length is associated with atherosclerosis (Khan *et al.*, 2012). Age-related musculoskeletal diseases have also been associated with telomere length. Chondrocytes from patients with osteoarthritis exhibit shorter telomere lengths than control patients; given that chondrocyte senescence causes changes known to accelerate osteoarthritis, it is possible that accelerated telomere loss might contribute to osteoarthritis (Li *et al.*, 2012). Some studies have indicated that shorter telomeres are associated with lower bone mineral density, a characteristic of osteoporosis (Li *et al.*, 2012). Other studies, however, have found no such association, and so associations between telomere length and age-related musculoskeletal diseases are challenging to identify and interpret. In mouse models, a number of other diseases appear to be telomere-dependent. Mice with short telomeres display a wide variety of phenotypes – these include: immune problems (opportunistic infections, impaired vaccine responses, and altered T-cell ratios), gastrointestinal problems (enterocolitis, villous blunting), defects in fibrosis following injury, and altered β -cell function leading to insulin resistance (Armanios and Blackburn, 2012). Many of the phenotypes observed in mice appear to be related to telomere-induced senescence. While most of the noncancer diseases with known telomere dependence in humans fall into the DC spectrum of disorders and phenotypes, the evidence in mice suggests that telomere-dependent senescence contributes to age-related diseases.

Eukaryotic Nucleotide Excision Repair

B Van Houten and M Kong, University of Pittsburgh, Pittsburgh, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

DNA polymerase A protein or protein complex which synthesizes a daughter strand of DNA using a parental strand as a template.

Helicase A protein which actively separates the two strands of DNA using the energy of adenosine triphosphate (ATP) hydrolysis.

Nucleotide excision repair (NER) A highly conserved multistep process in which several protein machines identify and remove bulky damage from DNA using a dual incision mechanism.

Perspective

Deoxyribonucleic acid (DNA) repair mechanisms have co-evolved with life, and maintaining genome integrity is essential for the health and fitness of any organism. One of the most highly conserved genome maintenance processes is nucleotide excision repair (NER). This repair pathway is found in all kingdoms of life and is critical for the removal of a wide variety of DNA lesions produced by environmental insult, including: ultraviolet (UV)-induced photoproducts, polycyclic aromatic hydrocarbons found in air pollution, toxins produced by fungi and plants, and several anticancer agents such as cisplatin.

NER was discovered in 1964 simultaneously in four laboratories under the direction of Richard Setlow, Paul Howard-Flanders, Robert Painter, and Philip Hanawalt (Boyce and Howard-Flanders, 1964; Kusumoto *et al.*, 2001; Pettijohn and Hanawalt, 1964; Setlow and Carrier, 1964). The first two studies showed the removal of UV-induced cyclobutane pyrimidine dimers (CPD) from bacterial and last two studies showed the incorporation of new nucleotides into the repairing sites in mammalian and bacterial cells, respectively. NER can be initiated in two general ways: (1) global genome repair (GGR), in which damage recognition proteins scan the entire genome for damaged sites and (2) transcription-coupled repair (TCR), in which RNA polymerase (RNAP) that has been stalled by a lesion in the transcribed strand recruits a DNA translocase, which functions to simultaneously backtrack RNAP from the damaged site and recruit DNA repair enzymes. This article explores the process of NER in human cells.

Mechanistically, NER occurs in four highly integrated steps (Figure 1):

1. Damage recognition, allows the initial identification of specific lesions in the context of chromatin.
2. Damage verification, in which the repair machinery assembles at sites of damage and uses ATP-driven processes to verify the damaged nucleotide.
3. Assembly of the incision complex, involving large conformational changes in both the DNA and protein complexes.
4. Excision, repair synthesis, and ligation, in which nucleases cleave two phosphodiester bonds both 5' and 3' to the

damaged nucleotide, releasing an oligonucleotide containing the damage during repair synthesis by DNA polymerases. DNA ligase then seals the resulting nick made at the repair patch.

Figure 1 Mechanism of global genome nucleotide excision repair. This molecular process can be viewed in four steps: (1) 'Damage recognition' occurs when XPC (blue)-HR23B (orange)-Centrin-2 (dark gray) bind to a lesion through XPC's beta-hairpins causing bending of the DNA; (2) 'Damage verification' is mediated by the recruitment of XPD (light green) and XPB (dark green) as part of TFIIH (gray), which loses the three protein CAK subunit (gray); (3) Once the DNA surrounding the lesion is opened the incision proteins, XPF-ERCC1 (dark purple-magenta) makes the 5' incision; and (4) DNA polymerase with the help of RFC (light red cylinder) and PCNA (blue ring) begin 'repair synthesis,' which signals to XPG to make the 3' incision and allow the 'excision' of the damage containing oligonucleotide and XPD. DNA 'ligase' (dark purple ring) seals the newly created repair patch.

As discussed more at the end of this article, deficiencies in several of these key proteins cause several human diseases characterized by increased sensitivity to sun light, premature aging, neurodegeneration, and in some cases highly elevated skin cancers. The entire process of human NER was reconstituted first from cell extracts and then from purified proteins in three different laboratories under the direction of Richard Wood, Aziz Sancar, and Jean-Marc Egly (Aboussekhra *et al.*, 1995; Araujo *et al.*, 2000; Mu *et al.*, 1995). Recent work by a number of laboratories has provided biochemical and structural insights into the nature of the proteins that mediate this complex process, which is reviewed in more detail (Scharer, 2013).

Damage Recognition

UV-DNA Damage Binding (DDB)

Photoproducts produced by sunlight are such ubiquitous DNA lesions, human cells have developed a specialized damage recognition complex, UV-DDB factor, which is a heterodimer consisting of DDB1 and DDB2 (encoded by xeroderma pigmentosum complementation group E (XPE) gene). DDB1 forms a complex with Culin4A and Rbx and is an ubiquitin-E3 ligase. UV-DDB has high affinity for UV-induced CPD, 6-4 photoproducts, and abasic sites; however, the physiological relevance of the latter lesion is not clear. UV-DDB initiates GGR and helps identify photoproducts in chromatin by adding ubiquitin moieties to histones, UV-DDB, and xeroderma pigmentosum complementation group C protein (XPC). It is believed that histone ubiquitylation facilitates nucleosome eviction providing access by the second GGR damage recognition protein, XPC-HR23B (Figure 2(a)). UV-DDB has been crystallized with DNA damage (Scrima *et al.*, 2008) and recent co-crystals with full-length human protein suggest that UV-DDB forms a dimer of dimers (DDB1-DDB2)₂ at damaged sites on two DNA molecules, in which the FQH domain of one of the DDB2 molecule probes the DNA for the damaged site, while the N-terminal domain of the other DDB2 contacts the DNA away from the lesion to help buttress the extremely stable interactions (Yeh *et al.*, 2012), Figure 3(a). Electron microscopy and atomic force microscopy have confirmed this mode of binding to DNA damage (Yeh *et al.*, 2012). This dimer is apparently remarkably stable on DNA, and it is believed that ubiquitylation is essential to allow UV-DDB to dissociate from damaged sites. However, multi-ubiquitylation steps leads to UV-DDB degradation and would thus prevent subsequent damage recognition. Recent data suggest that poly-ADP-ribose polymerase (PARP1) can PAR-ylate UV-DDB and allow it to cycle through multiple rounds of damage recognition (Pines *et al.*, 2012).

XPC-HR23B-CETN2

Damage recognition in genomic DNA is primarily achieved by a trimeric protein complex consisting of XPC, human Rad23B (HR23B), and centrin-2 (CETN2). It has been suggested that HR23B dissociates from XPC after damage recognition occurs (Bergink *et al.*, 2012). XPC-HR23B binds to a wide variety of

Figure 2 Initiation of NER at UV-induced photoproducts by UV-DDB or TCR. (a) Initiation of GG-NER on chromatinized DNA is achieved through lesion recognition by the UV-DDB heterodimer (DDB1 (green) and DDB2 (orange)). The E3 ubiquitin ligase CRL4DDB2, consisting of the UV-DDB heterodimer, Cul4A (purple), and Rbx1 (magenta), then ubiquitylates core histone as well as DDB2, leading to eviction of nucleosomes. (b) Transcription-coupled NER is initiated when transcribing RNAP (dark green) is stalled at the site of lesion and recruits CSB (orange). Binding of CSB recruits E3 ubiquitin ligase CRL4CSA, consisting of DDB1, CUL4, RBX1, and CSA (red). Stalled RNAP is then able to backtrack with the help of remodeling and sliding of upstream nucleosomes, facilitated by p300 (brown) and HMGN1 (purple). XAB2 (navy) in complex with XPA (yellow) are then recruited to site of lesion. Simultaneously, UVSSA (maroon) and USP7 (black) form complex at stalled RNAP, protecting it from degradation.

DNA lesions that differ in structure and conformation, and can even bind to helical distortions created by several mismatched bases (Kusumoto *et al.*, 2001; Sugasawa *et al.*, 2009; Sugasawa *et al.*, 2001). Further analysis showed that the ability of XPC-HR23B to open the DNA around the lesion correlated well with overall repair efficiency (Mocquet *et al.*, 2007). Structural analysis of the yeast XPC homolog, Rad4–Rad23 (see Table 1) showed that damage recognition is achieved by insertion of a beta-hairpin at the site of the damage (Figure 3(c)). However, the damage is flipped out of the helix and is disordered in the crystal structure (Min and Pavletich, 2007), indicating that XPC-HR23B makes large contacts with the non-damaged

Figure 3 Structural motifs involved in damage recognition and verification. Carbon backbone cartoon in various colors and space filling outline in gray are given for each structure. (a) Human UV-DDB (PDB ID: 4E5Z) consists of DDB1 (green) and DDB2 (red), the damage probing phenylalanine, glutamine, and histone wedge are shown in contact with the DNA as space-filled red spheres. (b) XPD (PDB ID: 4A15) from *Thermoplasma acidophilum* bound to a four-base oligonucleotide (shown in space filling); the iron sulfur center (space filled, brown and yellow) is shown in the blue domain; the arch domain is shown in green. (c) Rad4-Rad23 (PDB ID: 2QSH), the *Saccharomyces cerevisiae* homolog of XPC-HR23B is shown in green and magenta, respectively. The two beta-hairpins that make contact at and near the damaged site are shown in red and blue, respectively. DNA is shown in gold and blue. (d) XPB (PDB ID: 2FWR), from *Archaeoglobus fulgidus*. (e) Human XPA (PDB ID: 1XPA), structure of the core domain solved by NMR showing the zinc finger (zinc in magenta) and the presumed DNA binding loop XPA (red). (f) Human DNA ligase I (PDB ID: 1X9N) shown bound to DNA (gold and blue).

strand and does not make direct contact with the damaged bases. The fact that a beta-hairpin is used to interrogate the DNA by probing into the DNA nicely explains why several mismatched bases are sufficient for recognition by XPC-HR23B. Centrin-2, a EF-hand calcium binding protein, forms a complex with XPC-HR23B and has been shown to stimulate damage binding and repair (Krasikova *et al.*, 2012; Nishi *et al.*, 2005). Further analysis of Centrin-2 suggests that it may mediate the interaction of XPC-HR23B with xeroderma pigmentosum group A protein (XPA) (Nishi *et al.*, 2013).

Transcription-Coupled Repair

Many lesions which are acted on by NER also stall RNAP (Hanawalt and Spivak, 2008). Stalled RNAP represents a

critical problem to the DNA transaction machinery, as it can cause loss of critical gene expression, trigger apoptosis, and create replication blocks. Nature has dealt with this problem in a resourceful way by directing key motor proteins to push RNAP away from the lesion and simultaneously recruit the DNA repair machinery. Several key factors in human cells are involved in moving RNAP upstream from the damaged site. Cockayne syndrome A and B (CSA and CSB) proteins are recruited to the stalled RNAP. CSB is a chromatin remodeling protein with a helicase-like fold, and it interacts with CSA which forms a complex with DDB1-culin4A-RBX1 (CRL4), which can ubiquitylate both itself and CSB. A recently discovered protein UV-stimulated scaffold protein A (UVSSA), which has been found to be mutated in certain UV-sensitive humans (discussed below), forms a complex with ubiquitin-specific protease 7 (USP7), a deubiquitylating enzyme (Figure 2(b)). Together the CSB-CRL4^{CSA} complex helps recruit the XPA-binding protein XAB2, which is an essential protein for pre-mRNA (messenger RNA) splicing, to the stalled RNAP. XAB2 participates in repair by attracting XPA to the damaged site and may be necessary for RNAP to restart transcription after repair. Once XPA and TFIIF are recruited to the damaged site, repair proceeds as shown in Figure 1.

Damage Verification

Prior to making the commitment to incise and remove the DNA lesion and surrounding nucleotides, the cell works to process the damaged site into a new conformation in an energy-dependent step, involving ATP hydrolysis, through a kinetic proof-reading mechanism (Reardon and Sancar, 2004). This processing is mediated by the dual action of transcription-factor IIH (TFIIH) and XPA-RPA complex.

TFIIH

TFIIH is a multi-subunit protein complex consisting of two DNA helicases, xeroderma pigmentosum complementation group B protein (XPB) (Figure 3(d)), and xeroderma pigmentosum complementation group D protein (XPD) (Figure 3(b)); and a kinase domain (CAK), consisting of cyclin H (CCNH), cyclin-dependent kinase 7 (CDK7) and ménage a trois 1 (MNAT1) proteins, and five other scaffold proteins (Table 1). TFIIH is an interesting protein machine that has several roles in the nucleus (Svejstrup *et al.*, 1996). First, it functions in transcription by opening the promoter to allow RNAP initiation. Second, TFIIH functions in NER, by helping to open up the DNA around the lesion to allow damage verification (Oksenyich *et al.*, 2009). Finally, TFIIH, through its kinase domain, CAK, is directly involved in cell cycle regulation. The two helicases within TFIIH play different roles in each process. The 3' → 5' helicase activity of XPB is essential for transcriptional initiation, whereas XPB's ATPase and XPD's 5' → 3' helicase activity are essential for DNA damage verification and subsequent repair. TFIIH unwinds the DNA about 20 nucleotides around the DNA lesions. It has been shown that XPD makes direct contact at the damaged site and its helicase activity is inhibited by damage (Buechner *et al.*, 2014;

Table 1 Human and yeast nucleotide excision repair (NER) proteins

Human			Yeast			Function
Gene	AA	MW (kD)	Gene	AA	MW (kD)	
CCNH (cyclin H)	323	38	CCL1	393	45	Kinase subunit of TFIIH
CDK7 (cyclin-dependent kinase 7)	346	39	KIN28	306	35	Kinase subunit of TFIIH
CSA (ERCC8)	396	44	RAD28	515	57	Interaction with Cockayne syndrome type B (CSB) protein
CSB (ERCC6)	1493	168	RAD26	1085	125	A member of the SWI2/SNF2 family of ATP-dependent chromatin remodeling factors TCR
CETN2 (centrin-2)	172	20	CDC31	161	18	Interaction with XPC causing conformational changes
DDB1	1140	127				DDB subunit, with CUL4-RBX1 forms a E3 platform and interacts with various WD repeats proteins
CUL4A	667	78				Cullin4A, E3 ligase
RBX1	108	12				Ring-box 1, E3 ubiquitin protein ligase
XPE (DDB2)	427	48	PRP4	465	52	DDB subunit, defective in XPE
ERCC1	323	36	RAD10	210	24	Forms complex with XPF
XPF (ERCC4)	916	107	RAD1	1100	126	5' incision nuclease
FBL3 (FBXL2)	423	47	RAD7	565	64	With RAD16 forms E3 ubiquitin ligase and damage binding
GTF2H1	548	62	TFB1	642	73	TFIIH subunit
GTF2H2	395	44	SSL1			TFIIH subunit
GTF2H3	308	34	TFB4	338	37	TFIIH subunit
GTF2H4	462	52	TFB2	513	59	TFIIH subunit
GTF2H5 (TTDA)	71	8	TFB5	72	8	TFIIH subunit
LIG1	919	102	CDC9	755	84	DNA ligase
MMS19L (MMS19)	1030	113	MET18	1032	118	Required for transcription and NER
MNAT1	309	36	TFB3			TFIIH subunit
			RAD16	790	91	With RAD7 forms E3 ubiquitin ligase and damage binding
HR23A	363	40	RAD23	398	42	RAD23B paralog
HR23B	409	43	RAD23	398	42	Forms complex with XPC and binds distorted DNA
RPA1	616	68	RFA1	621	73	RPA subunit, binds ssDNA intermediates
RPA2	270	30	RFA2	273	30	Interaction with ssDNA intermediates
RPA3	121	14				Interaction with ssDNA intermediates
XAB2	1140	127	SYF1	859	100	Interaction with XPA
XPA	273	31	RAD14	371	43	Interaction with DNA and proteins of the pre-incision complex
XPB (ERCC3)	782	89	SSL2	843	95	3' to 5' helicase DNA helicase TFIIH subunit
XPC	940	106	RAD4	754	87	Interaction with distorted DNA as complex with RAD23B
XPB (ERCC2)	760	87	RAD3	778	90	5'-to-3' DNA helicase TFIIH subunit
XPG (ERCC5)	1186	133	RAD2	273	30	3' incision nuclease

Abbreviations: CSA, Cockayne syndrome A; CSB, Cockayne syndrome B; DNA, deoxyribonucleic acid; ERCC, excision repair cross-complementing; RPA, replication factor protein; ssDNA, single-stranded DNA; TCR, transcription-coupled repair; XPA, xeroderma pigmentosum group A protein; XPB, xeroderma pigmentosum complementation group B; XPC, xeroderma pigmentosum C protein; XPE, xeroderma pigmentosum E protein; XPF, xeroderma pigmentosum complementation group F protein; XPG, xeroderma pigmentosum complementation group G protein.

Mathieu *et al.*, 2013; Reardon and Sancar, 2002). It is thus believed that XPD provides damage verification by being directly inhibited by the DNA damage as it translocates in a 5'→3' direction on the damaged strand (Kuper *et al.*, 2012; Mathieu *et al.*, 2013). Recent data suggest that MNAT1 interacts directly with the arch domain of XPD turning off the helicase activity of XPD (Abdulrahman *et al.*, 2013). Thus, the CAK domain is a molecular switch that provides important

phosphorylation of RNAP and its release allows damage verification to proceed (Coin *et al.*, 2008).

XPA-RPA

XPA is a key protein in both GGR and TCR. XPA, while being a relatively small protein of 273 amino acids (Table 1), interacts

with many NER proteins, including: TFIIH, XPC-HR23B, DDB2, excision repair cross-complementing 1 (ERCC1), proliferation cell nuclear antigen (PCNA), and replication factor protein (RPA) (Scharer, 2013). RPA is a three-subunit protein which binds to single-strand DNA and apparently helps stabilize XPA binding to several DNA damaged substrates. The XPA-RPA complex has affinity for helically distorted DNA (Camenisch *et al.*, 2006; Missura *et al.*, 2001), and RPA is believed to make significant contact with the non-damaged strand (Mocquet *et al.*, 2008). XPA contains several interesting structural motifs including a zinc and a beta-hairpin; the latter is believed to be necessary for damage recognition, reviewed in Kuper and Kisker (2012); see Figure 3(e).

Assembly of the Incision Complex

TFIIH and XPA/RPA having verified the presence of a damaged nucleotide, serve as a scaffold for the recruitment of the two endonucleases, xeroderma pigmentosum complementation group F protein (XPF), and xeroderma pigmentosum complementation group G protein (XPG). Working in sequential fashion, XPF and XPG incise the damage strand facilitating the excision of the damage containing oligonucleotide.

XPF-ERCC1

XPF forms a heterodimeric complex with the ERCC1 protein. XPF-ERCC1 is a structure-specific endonuclease and is apparently recruited to the TFIIH verification complex through its interaction with XPA and RPA (Croteau *et al.*, 2008; Tripsianes *et al.*, 2007; Tsodikov *et al.*, 2007). It has been shown that mutation of two highly conserved residues in XPA (Asn-110 and Tyr-145) located in the XPA binding site of ERCC1 decreases overall NER activity, but does not decrease the nuclease activity of XPF-ERCC1 on model nuclease substrates consisting of single-strand/double-strand junctions (Orelli *et al.*, 2010). XPF-ERCC1's nuclease hydrolyzes the phosphodiester bond approximately 20 nucleotide 5' to the damaged site. XPF-ERCC1's nuclease activity is also necessary for the repair of interstrand DNA cross-links in a mechanism that is different from its role in NER (Clauson *et al.*, 2013). Since many anticancer drugs such as cisplatin are repaired by NER, it is interesting to note that high levels of ERCC1 mRNA, but not protein are correlated with worse prognosis in women with advanced-stage ovarian cancer (Deloia *et al.*, 2012).

XPG

XPG is the 3' nuclease and shares homology with the flap-endonuclease, FEN1 (Scharer, 2008). XPG is recruited to TFIIH, where its nuclease activity remains inactive. XPG is actually required for the recruitment and the stimulation of XPF-ERCC1's nuclease activity (Mocquet *et al.*, 2008). XPG is also a structure-specific nuclease and incises the approximately 5th phosphodiester bond 3' to the damaged site. However, XPG's incision activity is not stimulated until repair synthesis proceeds from the 5' nick generated by XPF-ERCC1 (Fagbemi *et al.*, 2011; Staresincic *et al.*, 2009).

Excision, Repair Synthesis, and Ligation

5' incision appears to be the signal for the recruitment of repair synthesis machinery which fills in the repair patch triggering XPG incision and oligonucleotide release and subsequent DNA ligation.

DNA Polymerases

Reconstitution experiments with purified proteins indicated that both DNA polymerases δ and ϵ in the presence of the clamp loader, replication factor C (RFC), and the polymerase accessory sliding clamp, PCNA were necessary to fill in the repair patch (Araujo *et al.*, 2000; Shivji *et al.*, 1995). Surprisingly, the error-prone translesion polymerase DNA polymerase κ has more recently been shown to participate in the gap-filling step of NER (Ogi and Lehmann, 2006). It has been suggested that 50% of the repair sites use DNA polymerases κ and δ to fill in the patch, while the other 50% require DNA polymerase ϵ (Ogi *et al.*, 2010). Cell cycle analysis suggests that DNA polymerase δ and κ are absolutely required in non-cycling cells, whereas DNA polymerase ϵ is used in cells that are rapidly proliferating. Excision of the oligonucleotide containing the damage is accompanied by the loss of TFIIH, and it appears that XPD stays bound to the excision product (Kemp *et al.*, 2012).

Ligation

DNA ligase I was first identified as the main ligase that is essential for sealing the newly synthesized repair patch (Figures 1 and 3(f)). However, recent studies suggest that in non-cycling cells DNA ligase III α and XRCC1 can help carry out the ligation step of NER (Moser *et al.*, 2007). These cell cycle effects have important implications in considering NER in the context of an entire organism in which many of the cells are terminally differentiated and nondividing.

Human Diseases

Because of the prevalence of endogenously and exogenously induced DNA damage, loss of several key NER proteins are the cause of a variety of rare human diseases (Hoeijmakers, 2001).

Cockayne Syndrome

Cockayne syndrome was first recognized in 1936 as patients with dwarfism, retinal atrophy, and deafness, and presents with a wide spectrum of symptoms that greatly differ in severity (Cockayne, 1936). These symptoms include cutaneous photosensitivity, cataracts, dental abnormalities, progressive neurodegeneration, mental retardation, developmental failure, deep sunken eyes, and progeroid appearance (Vermeulen and Foustieri, 2013). Mutations in several different genes can cause this syndrome; these include genes encoding CSA, CSB, XPB, XPD, and XPG proteins (Cleaver *et al.*, 2009).

Trichothiodystrophy

Trichothiodystrophy (TTD) was first described by Davies in 1968 as a rare autosomal syndrome in which patients exhibited sulfur-deficient brittle hair, scaly skin and mental, physical retardation, and in about 50% of the cases photosensitivity, without an elevation in skin cancer (Cleaver *et al.*, 2009; Pollitt *et al.*, 1968). Mutations in several genes encoding subunits of TFIIH, including the small 8 kDa subunit, XPB, and XPD can cause TTD. It has been suggested that this is a disease caused by dysfunction transcription (Bergmann and Egly, 2001; Coin *et al.*, 1998).

UV-Sensitive Syndrome

UV-Sensitive Syndrome (UVSS) was first observed in two Japanese siblings by Itoh *et al.* (1994). Patients with this syndrome display a three- to fourfold higher sensitivity to sunlight (Itoh *et al.*, 1994). Patients with this disorder display increased photosensitivity, telangiectasia, freckling, but no increase in skin tumors (Spivak, 2005). The genetics of UVSS are interesting in that mutations in CSA and CSB genes are responsible for some, but not all of the patients with this syndrome. Recently, the gene that causes UVSS-A was identified by exome sequencing and proteomics and was originally identified as KIAA1530, and is now called UVSSA gene (Fei and Chen, 2012; Nakazawa *et al.*, 2012; Schwertman *et al.*, 2012; Zhang *et al.*, 2012). The gene product interacts with CSA and CSB to help recruit USP7 to sites of TCR (Schwertman *et al.*, 2012). After damage UVSS-A binds to stalled RNAP, where it recruits USP7, which de-ubiquitinates CSB to help stabilize it at damage sites.

Xeroderma Pigmentosum

Xeroderma pigmentosum (XP) was first described by Kaposi and Ritter in 1870 and was characterized by flaky and hyper- and hypopigmentation of sun-exposed skins. XP patients show a remarkable sensitivity to sunlight with a 2000-fold increase in basal cell and squamous cell carcinomas (Cleaver *et al.*, 2009; Hoeijmakers, 2001). XP can be caused by mutations in one of seven genes encoding nucleotide excision repair proteins (XPA-G), or a mutation in a translesion DNA polymerase η that can bypass UV-induced pyrimidine dimers. Many of these XP patients (complementation groups A, B, D, and G) also show neurodegeneration (Cleaver *et al.*, 2009). It has been suggested that this neurodegeneration may be caused by the accumulation of rare forms of oxidative damage, cyclo-dA and cyclo-dG which are repaired by NER (Brooks *et al.*, 2000).

XFE (XPF-ERCC1) Progeria

Since ERCC1 and XPF help stabilize each other, as loss of one protein causes a concomitant loss of the other. Loss of either ERCC1 or XPF is associated with a premature aging phenotype (Niedernhofer *et al.*, 2006). Mice carrying a complete loss of ERCC1 show an inability to thrive, dwarfness, kyphosis, and neurological defects and died within 4 weeks of birth (Niedernhofer *et al.*, 2006). Hypomorphic mice expressing less than 20% of the normal levels of ERCC1 show a constellation

of phenotypes all of which are consistent with premature aging (Gregg *et al.*, 2011). It is believed that the aging defect is not due to loss of NER, but is due to the direct role of XPF and ERCC1 in the repair of interstrand cross-links (Clauson *et al.*, 2013). Taken together, these data suggest that endogenous metabolites such as lipid peroxidation can mediate interstrand cross-links which if not repaired can cause premature aging.

Acknowledgments

We would like to apologize to the many friends and colleagues whose work, in the interest of space, could not be included here. This work was supported by an NIH grant, R01ES019566.

Glossary

Haploinsufficiency The presence of only one functional copy of a gene in a diploid organism which is not sufficient for performing its complete functions, leading to an impaired or diseased state.

HeLa cells An immortal cervical cancer cell line originally isolated from a single patient, Henrietta Lacks, and commonly used in cell biology research.

Mouse embryonic fibroblasts Immortalized cell lines derived from mouse embryos. In this context, they allow researchers to study cells from knockout mice with an embryonic lethal phenotype.

Processivity factor Accessory protein which enhances the activity of an enzyme. For DNA polymerases, they prevent the dissociation of the enzyme from the DNA strand it is extending.

Maintenance of Genome Stability and the Role of Base Excision Repair

The chemical structure of DNA in all cells is subject to attack from both exogenous sources, such as ionizing radiation and environmental toxins, as well as endogenous sources, including cellular reactive oxygen species produced as a by-product of normal metabolism. Indeed, human cells have been estimated to suffer greater than 10 000 DNA base damage events per cell per day (Lindahl, 1993). Without a mechanism for repairing such alterations to DNA, these DNA base lesions have the potential to cause mutations, leading to the disruption of essential proteins and subsequently promote the development of diseases such as premature aging, metabolic diseases, neurodegenerative diseases, and cancer. The base excision repair (BER) pathway has evolved to correct a plethora of different small DNA base damage lesions through a coordinated process of several steps involving a specific enzyme, or class of enzymes, whose goal is to restore genome integrity and prevent disease development (Table 1). It is present in evolutionarily diverse organisms, from bacteria and yeast through to humans. Indeed, some of the BER enzymes were first discovered in *Escherichia coli* (Verly and Paquette, 1972; Lindahl, 1974). The individual steps and the enzymes involved are now well defined, and these can be broadly divided into: (1) DNA base damage recognition and removal,

(2) abasic site incision and processing of DNA strand break ends, (3) insertion of the correct undamaged nucleotide, and (4) DNA nick ligation. These will be described sequentially in more detail below.

Basic Overview of the BER Pathway

BER repairs small lesions to DNA, which fall into several categories (Figure 1). Broadly, these are: (1) oxidative DNA base damage caused by reactive oxygen species produced by cellular metabolism and ionizing radiation, (2) spontaneous hydrolysis of the glycosidic bond connecting the base with the phosphodiester backbone, a process called depurination, (3) deamination of bases (i.e., removal of NH_2 group), such as deamination of cytosine to uracil, although this cannot occur on thymine residues as they do not have an amine group, and (4) DNA base alkylation. Some of these DNA base lesions are known to be mutagenic, demonstrating the importance of their efficient removal from genomic DNA (Bjelland and Seeberg, 2003; Cooke *et al.*, 2003). For example, 8-oxoguanine can form base pairs equally well with cytosine, adenine, or thymine; depurination leaves a gap in the base sequence termed an abasic or apurinic/apyrimidinic (AP) site which can stall transcription; and deamination of cytosine to uracil can result in a change on the complementary strand from a guanine to an adenine base during DNA replication.

The initial step of BER is damage recognition by a base damage-specific DNA glycosylase enzyme. Once a damaged base is identified, the DNA glycosylase cleaves the *N*-glycosidic bond connecting the base to the phosphodiester backbone. This predominantly creates an AP site, where the base is missing, although a break in the DNA strand can also be generated depending on the DNA glycosylase involved. This AP site is usually recognized by AP endonuclease 1 (APE1) which incises the phosphodiester backbone to create a DNA single-strand break. Alternatively, depending on the type of DNA ends generated through specific DNA glycosylases, these ends require processing by APE1 itself, or by polynucleotide kinase phosphatase (PNKP). DNA polymerase β then fills the gap with the correct, undamaged nucleotide, using the base on the opposing strand as a template, and further processes the

Figure 1 Examples of small DNA base lesions. The chemical structures of the four undamaged DNA bases are presented, and their damaged derivatives which are considered in this article are listed below. The damaged bases are color-coded according to the type of damage suffered: oxidative damage (red), deamination (blue), or alkylation (green).

phosphodiester backbone. The remaining nick in the phosphodiester backbone is sealed by DNA ligase III α in complex with the scaffold protein X-ray cross-complementing protein 1 (XRCC1). This completes the pathway known as short-patch BER, in which a single nucleotide is removed and replaced (Figure 2). This is the main mechanism through which the majority (>80%) of DNA base damage is repaired (Dianov *et al.*, 1992; Dianov and Parsons, 2007). A small proportion of DNA base damage is repaired through the long-patch BER pathway, which will be discussed in more detail later in this article.

DNA Base Damage Recognition and Removal by DNA Glycosylases

The first step of BER is initiated by the excision of damaged bases from DNA by DNA glycosylases. Humans have 11 known DNA glycosylases, each specific to a particular class of base damage or a specific lesion (Table 2). These enzymes can be divided into four distinct families: (1) uracil DNA glycosylases (UNGs), (2) helix-hairpin-helix (HhH) glycosylases,

(3) endonuclease VIII-like (NEIL) glycosylases, and (4) methylpurine DNA glycosylases (Jacobs and Schar, 2012; Brooks *et al.*, 2013; Wallace, 2013). The DNA glycosylases can be further subdivided based upon their catalytic mechanism, either monofunctional (base excision only, leaving an intact phosphodiester bond) or bifunctional (base excision and phosphodiester bond cleavage). Nevertheless, these enzymes all share a common mechanism to assess whether a base is correct and undamaged, or alternatively damaged, whereby the DNA glycosylase runs along the DNA backbone assessing each base pair in turn. If a damaged DNA base is detected, this is excised by the DNA glycosylase using a so-called base-flipping mechanism. This involves rotating the base around the phosphodiester backbone axis to 180° relative to its normal orientation. This moves the damaged base into the enzyme's active site, where this interaction is stabilized by specific amino acid interactions between the DNA glycosylase and the DNA. Subsequently the *N*-glycosidic bond linking the damaged base to the phosphodiester backbone is cleaved, creating an AP site (Figure 3). Bifunctional DNA glycosylases are able to further cleave the phosphodiester backbone to create a DNA single-strand break.

Figure 2 Overview of short-patch BER. DNA glycosylases excise the damaged base, creating different products depending on their mechanism of action. (a) Monofunctional glycosylases create an AP site which is recognized and cleaved by APE1 generating 3'-hydroxyl and 5'-deoxyribose phosphate ends. The 5'-deoxyribose phosphate moiety is subsequently removed by DNA polymerase β . (b) Bifunctional glycosylases perform either β -elimination (left pathway) or β,δ -elimination (right pathway) where a 3'-phospho- α,β -unsaturated aldehyde or 3'-phosphate, respectively are generated in addition to a 5'-phosphate. The 3'-phospho- α,β -unsaturated aldehyde is excised by APE1 whereas the 3'-phosphate is excised by PNKP. Following DNA strand break processing, in all cases the correct base is inserted by DNA polymerase β and the nick is sealed by the DNA ligase III α -XRCC1 complex. dRP, deoxyribose phosphate; PUA, 3' phospho- α,β -unsaturated aldehyde.

UNGs

The major enzyme involved in the excision of uracil base damage from both single- and double-stranded DNA is UNG, which demonstrates a very high specificity for this type of base damage (Kavli *et al.*, 2002). Whilst the single-strand-selective monofunctional uracil-DNA glycosylase (SMUG1) suggests in its name that it has a preference for uracil in single-stranded DNA, in fact it can also excise the base damage from double-stranded DNA. Consequently, SMUG1 is thought to be a backup for UNG, although it also has distinct activity against derivatives of uracil base damage, such as 5-hydroxymethyluracil. Thymine DNA glycosylase (TDG) was originally discovered as an enzyme that can excise thymine from mismatches with guanine. However, its enzymatic activity is more efficient against uracil residues opposite guanine. In fact, TDG has a relatively broad substrate specificity, including 5-hydroxymethyluracil and 3,N⁴-ethenocytosine (Cortazar *et al.*, 2007). Methyl-CpG-binding domain protein 4, similar to TDG, is a mismatch-specific DNA glycosylase that is able to excise thymine, uracil, and 3,N⁴-ethenocytosine opposite guanine residues (Petronzelli *et al.*, 2000). All of the UNGs are monofunctional glycosylases, in that they only perform excision of the damaged base.

HhH DNA Glycosylases

This class of enzymes is characterized by the presence of a HhH structural motif contained within the protein. The 8-oxoguanine DNA glycosylase (OGG1), as the name suggests, is the major enzyme involved in the removal of 8-oxoguanine lesions from DNA when paired opposite cytosine (Boiteux and Radicella, 2000). This enzyme is important since adenine will preferentially pair opposite 8-oxoguanine, so in the next round of DNA replication the original guanine will be mutated to thymine (termed as G to T transversion). OGG1 can also excise formamidopyrimidine lesions from DNA. The importance of removing 8-oxoguanine residues from DNA is further highlighted by the existence of the MutY homologue (MYH) DNA glycosylase, which removes the adenine residues which have mispaired with 8-oxoguanine. This enzyme therefore allows for the subsequent replacement of adenine with the correct cytosine residue opposite 8-oxoguanine, in order that the latter can be excised by OGG1. Interestingly, MYH can also excise adenine residues when aberrantly base paired opposite guanine or cytosine. The endonuclease III homologue (NTH1) predominantly acts upon oxidized pyrimidine base damage, such as thymine glycol, 5-hydroxyuracil, and 5-hydroxycytosine (Aspinwall *et al.*, 1997). Both OGG1 and

Table 2 The human DNA glycosylases and their specificities

Name	Abbreviation	Accession no.	Escherichia coli orthologue	Classes		Major type of damage excised
8-Oxoguanine DNA glycosylase 1	OGG1	O15527	Fpg	HhH DNA glycosylases	Bifunctional (β -elimination)	8-Oxoguanine formamidopyrimidines
Endonuclease III-like 1	NTH1	P78549	Nth	HhH DNA glycosylases	Bifunctional (β -elimination)	Oxidative damage to pyrimidines, including thymine glycol, 5-hydroxyuracil, 5-hydroxycytosine

Thymine DNA glycosylase	TDG	Q13569	Mug	UNGs	Monofunctional	Thymine or uracil from mispairs with guanine
Uracil DNA glycosylase	UNG	P13051	Ung	UNGs	Monofunctional	Uracil residues

**Figure 3** Mechanism of action of damaged DNA base excision by DNA glycosylases. DNA glycosylases scan one strand of the double helix, probing each DNA base in turn. If they encounter a damaged base they can excise (in this case a uracil residue), this is flipped outside of the double helix to 180° relative to the phosphodiester backbone, and the *N*-glycosidic bond is cleaved. This releases the damaged base and creates an AP site.

NTH1 are bifunctional DNA glycosylases which carry out β -elimination, cleaving the phosphodiester backbone once (explained in Section NEIL DNA Glycosylases).

NEIL DNA Glycosylases

The NEIL DNA glycosylases consists of three family members, namely NEIL1, NEIL2, and NEIL3 (Wallace, 2013). When originally discovered, NEIL1 and NEIL2 were thought to act as backup repair enzymes to OGG1 and NTH1, since their substrates include oxidized pyrimidines (including thymine

glycol, 5-hydroxycytosine, and 5-hydroxyuracil), 8-oxoguanine, and formamidopyrimidine (Hazra *et al.*, 2002a, 2002b; Rosenquist *et al.*, 2003). However unlike OGG1 and NTH1, NEIL1 and NEIL2 can remove this type of base damage from single-stranded DNA and from bubble structures mimicking those that are formed during transcription or replication (Dou *et al.*, 2003), and NEIL1 can also excise DNA base damage in close proximity to another DNA lesion, which can be typically induced by ionizing radiation (Parsons *et al.*, 2005, 2007). NEIL3 also appears to remove oxidized pyrimidines and purines preferentially from single-stranded DNA and has been reported, in addition to NEIL1, to remove base damage from

quadruplex and telomeric DNA (Zhou *et al.*, 2013). This suggests a more specific and defined role for NEIL DNA glycosylases during the cell cycle. Importantly, these enzymes are bifunctional enzymes which carry out β,δ -elimination, cleaving the phosphodiester backbone twice (explained in Section Abasic Site Incision and Processing of DNA Strand Break Ends).

Methylpurine DNA Glycosylase

Methylpurine DNA glycosylase is specific for the removal of alkylated base damage from DNA. This includes the excision of 3-methyladenine, 7-methylguanine, and 3-methylguanine from both single- and double-stranded DNA (O'Connor, 1993). It is also capable of excising hypoxanthine and 1,N⁶-ethenoadenine.

Abasic Site Incision and Processing of DNA Strand Break Ends

Monofunctional DNA glycosylases only excise the damaged DNA base creating an AP site with an intact phosphodiester

backbone. The abasic site is subsequently recognized and processed by APE1, which hydrolyzes the phosphodiester bond between the phosphate moiety of the AP site and the deoxyribose moiety of the nucleotide 5' to the AP site (Figure 4(a); Demple *et al.*, 1991; Robson and Hickson, 1991). This creates a gap in the DNA strand which is flanked by a 3'-hydroxyl group and a 5'-deoxyribose phosphate, which is what remains of the original damaged nucleotide. This is important as the next step in the BER pathway, nucleotide incorporation by a DNA polymerase, requires a 3'-hydroxyl end so that the new, undamaged and correct nucleotide can be added.

Bifunctional DNA glycosylases possess an additional activity that cleaves the phosphodiester backbone creating a DNA strand break that is flanked by different DNA ends depending on the DNA glycosylase employed. Following bifunctional DNA glycosylase action, the 3'-end of the strand break requires further processing in order to generate the 3'-hydroxyl end necessary for downstream DNA polymerase action. OGG1 and NTH1 perform β -elimination, leaving the DNA strand break flanked by a 3'-phospho- α,β -unsaturated aldehyde and a 5'-phosphate. Therefore the 3'- α,β -unsaturated

Figure 4 Monofunctional and bifunctional glycosylases generate different DNA ends. (a) Monofunctional DNA glycosylases only excise the damaged base, leaving an AP site with an intact phosphodiester backbone. This is then processed by APE1, which generates 3'-hydroxyl and 5'-deoxyribose phosphate ends, the latter of which is excised by the lyase activity of DNA polymerase β generating a 5'-phosphate end. (b) Bifunctional DNA glycosylases which perform β -elimination also cleave the phosphodiester backbone, in addition to damaged DNA base removal, leaving a 3'-phospho- α,β -unsaturated aldehyde and a 5' phosphate. APE1 processes the 3'-end to leave a 3'-hydroxyl group. (c) Bifunctional DNA glycosylases which perform β,δ -elimination generate 3'-phosphate and 5'-phosphate ends. PNKP subsequently processes the 3'-phosphate to generate a 3'-hydroxyl end.

aldehyde requires removal to generate a 3'-hydroxyl end, and in fact this is performed by the action of APE1 (Figure 4(b)). In contrast, the NEIL family of bifunctional DNA glycosylases performs β,δ -elimination which through two cleavages creates a DNA strand break flanked by a 3'-phosphate and a 5'-phosphate. The 3'-phosphate end requires processing to generate a 3'-hydroxyl end by a different enzyme, called PNKP (Figure 4(c); Wiederhold *et al.*, 2004).

Insertion of the Correct Undamaged Nucleotide

The end product of AP site incision and DNA strand break processing is the generation of a single nucleotide gap that contains a 3'-hydroxyl end which is a substrate for DNA polymerase. The major DNA polymerase employed during BER is DNA polymerase β (Sobol *et al.*, 1996). Although it is not a replicative DNA polymerase, its incorporation of a new nucleotide into the repair gap follows the same basic mechanism. Energy is released as pyrophosphate from the reaction between the incoming deoxyribonucleoside phosphate and the 3' hydroxyl group of the nucleotide immediately upstream. As with DNA replication, the fact that the genomic sequence is encoded on two strands is essential, as the undamaged strand opposite the repair site is used as a template to determine which nucleotide to insert.

Despite the successful replacement of the damaged nucleotide with the correct undamaged one, if BER was initiated by a monofunctional DNA glycosylase, the repair site still contains a 5'-deoxyribose phosphate moiety which cannot be ligated to the proximal 3'-hydroxyl end. In fact, in addition to nucleotide incorporation, DNA polymerase β also contains lyase activity which simultaneously removes the 5'-deoxyribose phosphate to generate the correct 5'-phosphate end (Figure 4(a); Matsumoto and Kim, 1995; Allinson *et al.*, 2001). BER which has proceeded through a pathway initiated by a bifunctional DNA glycosylase will already have this 5'-phosphate end, and so no further processing is required in this case (Figures 4(b) and 4(c)).

DNA Nick Ligation

Although the genetic sequence has now been corrected following DNA polymerase β action, there still remains a DNA single-strand break 3' to the inserted nucleotide. Therefore the phosphodiester backbone must be sealed in order to restore the genetic integrity of the DNA. This step is performed by a DNA ligase and is dependent on adenosine triphosphate (ATP), which activates the 5'-phosphate on the inserted nucleotide. This makes the reaction with the 3'-hydroxyl on the other side of the single-strand break energetically favorable, and so the nick is sealed with the release of adenosine monophosphate. The major DNA ligase employed during BER is DNA ligase III α , which is actually in a stable complex with the scaffold protein XRCC1 (Cappelli *et al.*, 1997; Nash *et al.*, 1997). The XRCC1-DNA ligase III α complex therefore binds the DNA strand break and ligates the nick in an ATP-dependent process.

As described previously, the BER process described above is commonly referred to as the short-patch BER pathway, since

the DNA base damage is replaced by a single, correct, undamaged nucleotide, and is the predominant mode of BER.

The Long-Patch BER Pathway

In some instances, particularly following the formation of reduced or oxidized abasic sites, the 5'-deoxyribose phosphate group produced by the action of APE1 is resistant to processing by the lyase activity of DNA polymerase β . Consequently the XRCC1-DNA ligase III α complex is then unable to ligate the nick containing this 5'-end blocking group. In this case an alternative pathway called long-patch BER is employed. Following incorporation of the correct, undamaged nucleotide by DNA polymerase β , there is then a polymerase switch to the replicative DNA polymerases δ or ϵ (Frosina *et al.*, 1996; Podlutzky *et al.*, 2001). These replicative polymerases then synthesize two to eight more nucleotides into the repair gap from the 3'-end, therefore displacing those already in position to form a 5'-flap structure (Figure 5). The processivity factor,

Figure 5 Overview of long-patch BER. If the lyase activity of DNA polymerase β is unable to process the 5' end once the correct nucleotide is inserted, long-patch BER is performed. This involves the addition of 2–8 more nucleotides into the repair gap by DNA polymerase δ or ϵ causing strand displacement and the formation of a 5'-flap structure. This structure is cleaved by flap endonuclease 1 (FEN1) before the nick is sealed by DNA ligase I. PCNA acts as a stabilizing factor throughout these steps.

proliferating cell nuclear antigen (PCNA), is additionally required for the correct function of DNA polymerase δ and ϵ . The 5'-flap structure produced during long-patch BER is consequently recognized and removed by the enzyme flap endonuclease (FEN1) to leave a single-strand break flanked by 3'-hydroxyl and 5'-phosphate ends (Klungland and Lindahl, 1997). This single-strand break is consequently sealed by DNA ligase I, in concert with PCNA, in an ATP-dependent process. This is in contrast to the XRCC1–DNA ligase III α complex that is specific to the short-patch BER pathway.

The Importance of Key BER Proteins is Highlighted by Knockout Mouse Models

Several mouse knockout models of BER proteins have been attempted in order to elucidate in detail their functions and roles in genome stability and the etiology of human diseases such as premature aging, metabolic diseases, neurodegenerative diseases, and cancer. A trend has emerged where deletion of the proteins which are essential for a particular step of BER causes embryonic lethality, demonstrating they are essential for organisms to develop and function at a cellular level. For example, mouse knockouts of APE1 (Xanthoudakis *et al.*, 1996), DNA polymerase β (Sobol *et al.*, 1996), DNA ligase III (Puebla-Orsorio *et al.*, 2006), XRCC1 (Tebbs *et al.*, 1999), and FEN1 (Kucherlapati *et al.*, 2002) are all embryonic lethal. Even in mouse haploinsufficiency models, containing only a single functional copy of the gene of interest, higher levels of spontaneous tumors and a high sensitivity to DNA damaging agents are seen in relation to APE1, DNA polymerase β , and XRCC1 (Cabelof, 2012). Mouse embryonic fibroblasts have been generated from BER-deficient embryos with a lethal phenotype and used for further studies to finely dissect the cellular effect of lacking these key BER proteins. These cells likewise usually display hallmarks of genomic instability. For example, both XRCC1 and DNA polymerase β -deficient mouse embryonic fibroblasts are hypersensitive to DNA damaging agents (Horton *et al.*, 2008). Cumulatively, this further underlines the crucial role that key BER proteins play in genome stability and in the prevention of human diseases, such as cancer.

Interestingly, knockout models of individual DNA glycosylases are not embryonic lethal (Parsons and Elder, 2003). This is not surprising given as there are multiple DNA glycosylases which can initiate BER, and there is a large degree of overlap in their substrate specificities (Table 2). However, some DNA glycosylase-knockout mice do show an increased propensity to DNA damage and indeed some develop specific phenotypes, indicating it is advantageous to possess each member of the family of DNA glycosylases. For example, OGG1-knockout mice demonstrate an increased level of 8-oxoguanine and formamidopyrimidine lesions but do not appear to be prone to a significant elevation in spontaneous tumor formation (Klungland *et al.*, 1999). Likewise, NTH1-deficient mice reveal no phenotypic abnormalities (Ocampo *et al.*, 2002; Takao *et al.*, 2002). In contrast, NEIL1-knockout mice develop an obese phenotype associated with a metabolic syndrome (Vartanian *et al.*, 2006), which was also recently reported in the OGG1-deficient mice (Sampath *et al.*, 2012), but do not develop spontaneous tumors. The theory of

overlapping DNA base damage substrate specificity being a cause for the lack of phenotype in DNA glycosylase-knockout mice is further strengthened by the isolation of NEIL1/NTH1 double knockout mice. These animals develop spontaneous pulmonary adenomas and carcinomas and hepatocellular carcinomas at a higher rate than in the corresponding single gene knockout mice (Chan *et al.*, 2009).

Regulation of BER Protein Levels

Consistent with the essential role of key BER proteins, such as XRCC1 and DNA polymerase β , in genome stability and normal development as displayed by embryonic lethality in knockout mouse models, BER proteins are usually very tightly regulated. One of the major mechanisms through which this can be achieved is by protein post-translational modifications. Indeed, phosphorylation and acetylation of BER proteins has been observed (Almeida and Sobol, 2007). However, more recently it has emerged that one of the major mechanisms of regulating cellular levels of BER proteins is through ubiquitylation (Parsons and Dianov, 2013; Edmonds and Parsons, 2014). Ubiquitylation involves the addition of the small protein ubiquitin (8 kDa), either singularly (monoubiquitylation) or through linked ubiquitin chains (polyubiquitylation), to specific lysine residues on target proteins. Ubiquitylation is, however, a reversible process with the addition and removal of ubiquitin catalyzed by different families of enzymes, E3 ubiquitin ligases and deubiquitylation enzymes, respectively. The major function of polyubiquitylation is in targeting proteins for degradation by the proteasome. Ubiquitylation of many BER proteins employed during the various stages of the pathway is increasingly being reported, although particularly significant progress has been made in our understanding of the role of ubiquitylation in regulating DNA polymerase β . Specifically, the E3 ubiquitin ligase Mule has been shown to monoubiquitylate DNA polymerase β which retains the protein in the cytoplasmic compartment of the cell (Parsons *et al.*, 2009), enabling another E3 ubiquitin ligase enzyme called CHIP to polyubiquitylate it and target the protein for degradation (Parsons *et al.*, 2008). In contrast, the deubiquitylating enzyme ubiquitin specific protease 47 (USP47) can remove these ubiquitin molecules and reverse their effects, therefore allowing DNA polymerase β protein levels to accumulate and enter the nucleus to assist in DNA repair during genotoxic stress conditions (Parsons *et al.*, 2011). This ensures that cells are able to immediately respond to the induction of DNA damage, and avoid genomic instability. Further post-translational modifications of BER proteins are increasingly being identified as a major mechanism for controlling BER protein cellular localization, activity, and cellular levels. These mechanisms are important in the maintenance of genome stability in the cellular response to DNA damage and, ultimately, in the survival of the organism.

Conclusions

- Maintenance of genome stability is an essential function of cell biology.

- Small base lesions to DNA are repaired by the BER pathway.
- BER is a tightly coordinated process involving the sequential action of a subset of enzymes from specific families.
- DNA glycosylases have distinct but overlapping specificities for different types of DNA base damage.
- Short-patch BER is the predominant mode, where only the single damaged nucleotide is replaced.
- Long-patch BER, involving the replacement of several nucleotides, may be employed when the DNA ends are resistant to DNA polymerase β processing.
- Disruption of the key enzymes involved in BER leads to embryonic lethality in mouse models and increased sensitivity to DNA damaging agents in deficient cells, correlating with an increased risk of development of diseases such as cancer.
- The cellular levels of BER proteins are regulated by post-translational modifications in response to DNA damage levels.

Introduction

DNA in each mammalian cell accumulates various types of lesions every day. DNA damage may be due to external agents like exposure to ultraviolet, ionization radiation, or internal agents like reactive oxygen species generated during metabolic or hydrolytic processes. These lesions can lead to break or breaks in strand or strands of DNA, an alteration in its chemical structure, loss, or a chemical change in a base of DNA. DNA damage if left unrepaired or incorrectly repaired may lead to genomic instability and chromosomal aberrations, eventually leading to cell death or cancer. Therefore, multiple repair pathways and complex DNA damage responses that recognize and repair these DNA damages have evolved to maintain the continuity and integrity of the genome.

Among various damages, DNA double-strand break repair (DSBR) is considered as the most lethal, as unrepaired double-strand breaks (DSBs) can lead to chromosomal translocations and consequently, cancer. Homologous recombination (HR) and nonhomologous DNA end joining (NHEJ) are two distinct pathways for the repair of DSB. HR, in general, requires regions of extensive homology and hence is conservative in nature and is the predominant pathway for DSBR in bacteria and lower eukaryotes. NHEJ, on the other hand, involves end-to-end ligation of the DNA termini accompanied by end editing with little or no requirement of homology.

NHEJ is considered as the major DSB repair pathway in higher eukaryotes and is believed to be active throughout the cell cycle. During lymphocytic development, both B-cells and T-cells utilize NHEJ to generate diversity in their repertoire of B-cell receptors and T-cell receptors, respectively. Even during maturation phase of B-cells for the generation of antibodies during class switch recombination, NHEJ plays a vital role. The mechanism and proteins involved in NHEJ is still an active area of research. Extensive genetic (using cell lines that were radiosensitive due to defective DSB repair) and biochemical studies led to the discovery of various NHEJ proteins, which have provided novel insights into the mechanism of NHEJ.

Mechanism of NHEJ

Recognition of DSBs

KU heterodimer that consists of two subunits, KU70 and KU80, is important for binding to DNA ends, once a DSB occurs during G0, G1, or early S phase of cell cycle (Figure 1; Chu, 1997; Dynan and Yoo, 1998). Interestingly, there appears to be a competition between HR and NHEJ machinery during late S and G2 phase (Bunting *et al.*, 2010; Adachi *et al.*, 2001; Sonoda *et al.*, 2006). KU complex along with DNA-PKcs gets activated upon binding to DNA, leading to a change in the conformation of KU (Lieber *et al.*, 2006). The crystal structure of KU heterodimer complexed with DNA showed that it has

toroidal shape with a hole for DNA (Walker *et al.*, 2001). Positively charged amino acids line the asymmetrical ring which interact with negatively charged phosphate backbone of DNA which allows DNA end-dependent movement of KU to interior of DNA (Walker *et al.*, 2001). Hence, KU heterodimer in association with DNA-PKcs forms a synaptic complex which helps in bringing the broken ends together (Bliss and Lane, 1997; Cary *et al.*, 1997; Ramsden and Gellert, 1998). However, some studies also suggested that recruitment of KU and DNA-PKcs could follow any order (Nick McElhinny *et al.*, 2000). Interestingly, mathematical modeling of this pathway has shown that DSB repair is similar, irrespective of the order as long as any protein is not rate-limiting (Li and Cucinotta, 2011). Very recently, another protein PAXX (paralog of XRCC4 and XLF) has been discovered which has been shown to interact with KU and may help in assembling core NHEJ factors on damaged chromatin (Ochi *et al.*, 2015).

Nucleolytic Processing by ARTEMIS–DNA-PKcs Complex

As explained before, KU slides internally after bringing the two DNA ends together, which leads to the contact of DNA-PKcs with DNA (Figure 1). This results in the activation of its serine/threonine kinase activity (Chu, 1997; Yoo and Dynan, 1999; Hammarsten *et al.*, 2000; Ma *et al.*, 2002). Once activated it phosphorylates itself as well as ARTEMIS. It has been shown that phosphorylated ARTEMIS along with DNA-PKcs can act as an endonuclease that can cleave 5'-overhangs, 3'-overhangs, and other DNA structures. It can also cleave hairpin intermediates of V(D)J recombination (Ma *et al.*, 2002, 2004, 2005; Yannone *et al.*, 2008). Additionally, ARTEMIS possesses an exonuclease activity by itself (Ma *et al.*, 2005). Hence, both the exonuclease and endonuclease activity of ARTEMIS is utilized in processing the ends (Ma *et al.*, 2002; Niewolik *et al.*, 2006).

Template-Dependent and Template-Independent DNA Synthesis

Once the ends are processed, they are end-filled using polymerases POL λ , POL μ , and terminal deoxynucleotidyl transferase (TdT), in order to make them ligatable (Figure 1). These polymerases belong to POLX family and they contain C-terminal portion of the BRCA-1 gene (BRCT) domain. The role of this family in NHEJ has been shown in both yeast and mammalian cells by genetic and biochemical studies. Efficacy and efficiency of fill-in synthesis varies between POL λ (fill-in of 5' overhangs) and POL μ (fill-in of 3' overhangs) (Lieber *et al.*, 2008). TdT has a major role during V(D)J recombination (Lieber, 2010).

Ligation

Once the ends are processed, they are ligated using DNA Ligase IV. The stability of Ligase IV is enhanced by XRCC4 (X-ray

Figure 1 Mechanism of NHEJ. DSBs are generated either physiologically during V(D)J recombination etc. or pathologically by ionizing radiation, free radicals etc. Once a DSB is generated and is committed to repair by NHEJ, KU70/KU80 heterodimer is recruited to the break. This not only inhibits nucleolytic process but also helps in recruitment of DNA-PKcs, which autophosphorylates and then phosphorylates Artemis. Endonucleolytic activity of Artemis processes the DNA ends followed by strand synthesis by Pol μ or Pol λ , the Pol X family members. XLF–XRCC4–Ligase IV is recruited to the DNA ends to ligate DNA ends. PAXX may interact with XRCC4 and XLF to mediate ligation.

repair cross-complementing protein 4) that stimulates adenylation and helps DNA Ligase IV to interact with DNA (Grawunder *et al.*, 1997; Schar *et al.*, 1997; Teo and Jackson, 1997; Wilson *et al.*, 1997; Modesti *et al.*, 1999). The activity of XRCC4–Ligase IV is further stimulated by XLF (XRCC4-like factor) (Ahnesorg *et al.*, 2006; Buck *et al.*, 2006; Callebaut *et al.*, 2006). Interestingly, XRCC4–Ligase IV can ligate one strand of DNA irrespective of the other strand (Gu *et al.*, 2007a,b) and is also dependent on sequence of overhangs (Gu *et al.*, 2007a,b). It has also been shown that PAXX works along with XRCC4 and XLF (Ochi *et al.*, 2015). Therefore, XLF–XRCC4–PAXX–Ligase IV complex plays a very important role in ligating incompatible DNA ends efficiently (Figure 1).

A-NHEJ

Another distinct and highly error-prone but less-characterized pathway that has been shown to join DSBs in the absence of key NHEJ factor, has been named as A-NHEJ or backup NHEJ or microhomology-mediated end joining (MMEJ) (Figure 2).

A-NHEJ has been believed to have a role in chromosomal translocations and genomic instability.

A-NHEJ pathway was first identified when mice deficient for *p53* and *Xrcc4* showed co-amplification of *c-Myc* and *IgH* locus from pro-B lymphomas (Zhu *et al.*, 2002). Earlier studies have shown that this pathway was dominant only when key NHEJ proteins like XRCC4 or Ligase IV were absent (Yan *et al.*, 2007; Corneo *et al.*, 2007; Guirouilh-Barbat *et al.*, 2007). Although little is known about the detailed mechanism and protein components, potential role of MRE11–RAD50–NBS1, PARP1, PARP2, DNA Ligase III α , and WRN in A-NHEJ has been shown (Figure 2; Dinkelman *et al.*, 2009; Deriano *et al.*, 2009; Robert *et al.*, 2009; Sallmyr *et al.*, 2008). Although the existence of this distinct pathway in normal mammalian cells is being explored (Truong *et al.*, 2013) its existence as a separate DSB repair pathway is still not clear (Pannunzio *et al.*, 2014).

Choice of DSB Repair Pathway

Since both NHEJ and HR are an absolute requirement for repairing DSBs, the choice of one pathway over the other

Figure 2 Probable mechanism of alternative or backup NHEJ. Once a DSB is generated in the absence of a key NHEJ factor, proteins like MRE11, NBS1, and PARP1 are recruited. This may further help in homology search and deletions at the ends. Phosphodiester bonds are recreated to maintain the continuity of genome by DNA Ligase I or III.

depends on factors like cell cycle, end resection, or DSB end structure. The availability of a homologous template during post-replicative stages of S phase makes HR the predominant pathway in S phase while condensed chromatin makes homology search difficult in G2-M phase restricting its dominance (Figure 3). It was recently shown that phosphorylation of 53BP1 along with Rif1 inhibit the recruitment of BRCA1 during G1 and hence limiting end resection thereby promoting NHEJ (Figure 3; Chapman *et al.*, 2013; Zimmermann and de Lange, 2014). On the other hand, upon phosphorylation of CtIP during S and G2 phases, end resection is activated promoting HR (Yun and Hiom, 2009).

NHEJ and Disease

Since NHEJ is an imprecise mode of joining, the ligated DNA molecules may have some loss of nucleotides 'information scar' which may accumulate in the genome and contribute to biological aging (Lieber *et al.*, 2008). A subset of such mutations may lead to excessive cellular proliferation or cancer. On the other hand, it is also known that *XRCC4* or *Ligase IV* knock out mice are embryonically lethal (Barnes *et al.*, 1998). It has been observed that cells possessing either mutations or altered levels of key NHEJ proteins render them radiosensitive and predispose them to cancer (Marangoni *et al.*, 2000; Riballo *et al.*, 1999; van der Burg *et al.*, 2009). Role of Ligase IV, XLF, and Artemis has been implicated in genetic disorders, namely, Ligase IV syndrome, immunodeficiency, and radiosensitive SCID (Rass *et al.*, 2007). Hence, deregulation of repair proteins

may lead to genomic rearrangements, higher mutations, and survival advantages to cancer cells (Lieberman, 2008; Powell and Bindra, 2009). In fact, KU and DNA-PKcs were found to be over-expressed in oral squamous, lung carcinoma, and breast, gastric and esophageal cancers. In essence, NHEJ proteins can be targeted to sensitize tumor cells (Srivastava and Raghavan, 2015).

NHEJ and Inhibitors

Small-molecule inhibitors are currently being developed which can lead to the death of cancer cells. One of the earliest inhibitors, wortmannin, an inhibitor of DNA-PKcs was not selective and acts as a pan PI3K inhibitor (Oliveira *et al.*, 2002). LY2940002 is another PI3K inhibitor known to inhibit DNA-PKcs (Rosenzweig *et al.*, 1997). NU7026 was then identified as a selective and potent inhibitor of DNA-PK (Willmore *et al.*, 2004). Since inhibition at an early stage of NHEJ may divert DSB repair toward alternative pathways, blocking DNA Ligase IV would lead to accumulation of DSBs, leading to apoptosis. Although L189 was developed as a potential Ligase IV inhibitor, it was active against all three ligases, Ligase I, III, and IV (Chen *et al.*, 2008). Recently, a selective inhibitor of Ligase IV, SCR7, was discovered which inhibited NHEJ both *in vitro* and *in vivo* (Srivastava *et al.*, 2012). It showed significant tumor regression in mouse tumor models and improved the efficacy of radio and chemotherapy, when coadministered (Srivastava *et al.*, 2012). It has been shown that encapsulated SCR7 (ESCR7) was fivefold better than its

Figure 3 Factors determining choice of DSB repair pathways. Numerous regulatory mechanisms are involved in choosing NHEJ as the double strand repair pathway for the repair of break. During S or G2 phase of the cell cycle, HR is the preferred pathway as the sister chromatid is readily available. Cell-cycle-dependent kinases (CDKs) phosphorylate CtIP that along with BRCA1 helps in end resection to initiate HR. Although NHEJ is active throughout the cell cycle, it plays a vital role during M or G1 phase. Phosphorylation of Rif1 by 53BP1 inhibits BRCA1 that contains end resection by Mre11/EXO1/BLM. This leads to recruitment of KU to the DNA ends and initiating NHEJ.

parental form (John *et al.*, 2015a,b). Thus, different therapeutic strategies need to be developed using DSB repair as a target selectively against cancer cells.

Glossary

Crossover/noncrossover Homologous recombination can lead to reciprocal exchange of DNA sequences flanking a recombination event (crossover) or not (noncrossover).

D-loop Primary DNA strand invasion product by the Rad51-ssDNA filament, which involves the formation of hDNA.

hDNA Hybrid DNA or heteroduplex (hDNA) refers to duplex DNA generated by DNA strand invasion during recombination. In case this involves a DNA sequence difference, hDNA may be subjected to mismatch repair, which may lead to gene conversion. Absence of mismatch repair maintains different genetic information on the Watson and Crick strands of the duplex DNA.

Hemi-catenane Specific topological entanglement of duplex DNA involving two single-strands of each duplex (see step 7c in [Figure 1](#)).

Holliday junction, double Holliday junction Four-stranded cross-strand structures mediated by homologous recombination. While single HJs can only be resolved to crossover or noncrossover outcome, dHJs can be resolved to crossover or noncrossover outcomes as well as dissolved to noncrossover outcome (see step 6a and ensuing steps in [Figure 1](#)).

Resolution/dissolution Resolution refers to the processing of recombination-mediated joint molecules by nucleases, whereas dissolution refers to alternative processes that do not involve nucleases.

Introduction

Exogenous DNA damage caused by radiation and environmental sources as well as endogenous DNA damage as a result of cellular metabolism (e.g., reactive oxygen species) or replication-associated genotoxic stress require constant attention by DNA damage repair and tolerance mechanisms ([Friedberg et al., 2006](#)). Homologous recombination (HR) comprises a number of distinct but related sub-pathways ([Figure 1](#)) that provide high-fidelity repair or tolerance of DNA damage by taking advantage of Watson–Crick base-pairing principles in a template-dependent fashion. The fundamental reaction involves DNA strand exchange that enables a 3'-DNA end engaging a suitable template for DNA synthesis to repair or bypass DNA damage and accurately restore contiguous chromosomes ([Figures 1–3](#)). Besides its direct role in repairing complex DNA damage such as DNA double-stranded breaks (DSB; [Figure 1](#)), DNA gaps ([Figure 2](#)), interstrand cross-links (ICL; [Figure 3](#)), and protein–DNA cross-links, HR also interfaces with DNA replication ([Figure 2](#)) and telomere maintenance ([Figure 1](#)) to ensure faithful duplication of the genome. This article focuses on the role of HR in somatic DNA damage repair and tolerance, drawing mostly from studies performed with budding yeast and humans. HR also plays a key role in meiotic chromosome segregation. In the section 'further reading,' the reader is referred to outstanding reviews that highlight specific aspects of HR in somatic DNA repair as well as its essential role in meiosis.

The Core Mechanism of Homologous Recombination

The core mechanism of HR involves generating single-stranded DNA (ssDNA) that allows assembly of the Rad51-ssDNA filament, which catalyzes the signature reactions of homology search and DNA strand invasion. DSB end-processing is well

understood and involves two successive resection steps: short-range resection by the Mre11–Rad50–Xrs2 complex (MRX; human MRE11–RAD50–NBS1; see [Table 1](#)) and long-range resection carried out by two partially overlapping pathways ([Figure 1](#), step 1). It is currently unclear, whether replication-associated gaps require processing ([Figure 2](#), step 3c).

DSB Resection

The MRX complex (human MRN; [Table 1](#)) initially recognizes and binds to DSBs ([Lisby et al., 2004](#)). The MRX complex integrates end-processing, DNA tethering, and signaling functions ([Stracker and Petrini, 2011](#)). Mre11 displays endonuclease and 3'–5' exonuclease activities that are essential for end-processing, when breaks contain chemically modified ends or bound proteins. RAD50 is an SMC-family protein with a long coiled-coil domain that can tether two DSB ends or different DNA molecules. Xrs2 (NBS1 in human) recruits the Tel1 kinase (human ATM) to the MRX complex to trigger the DNA damage response signaling cascade in response to DSBs. Sae2 (human CtIP) associates with the MRX (human MRN) complex, and it is still unclear whether it acts as a nuclease-cofactor or contains autonomous nuclease activity.

The initial short-range resection by MRX/Sae2 (human MRN/CtIP) appears to initiate with an endonucleolytic nick 50–100 nucleotides distant from the DSB ([Symington, 2014](#)). The Mre11 3'–5' exonuclease activity removes the terminal 5'-ending oligonucleotides resulting from the endonucleolytic incision. Following the initial short-range resection mediated by MRX/Sae2 (human MRN/CtIP), the broken DNA ends undergo additional long-range resection, generating long stretches of ssDNA. Two different pathways are involved in the long-range 5'–3' resection of the DSB ([Mimitou and Symington, 2008](#); [Zhu et al., 2008](#)). The processive 5'–3' exonuclease EXO1 defines the first long-range DSB resection pathway. The second pathway is significantly more complex and involves the

Figure 1 Pathways of DNA double-strand break (DSB) repair. DSBs are repaired using three different pathways. Single-strand annealing (SSA, red box) requires direct DNA sequence repeats flanking the DSB. After DNA end resection, the homologous sequences anneal leading to deletion of one repeat and of the intervening sequences. Nonhomologous end-joining (NHEJ, yellow box) rejoins broken ends by ligation in a template-independent manner with variable fidelity that depends on the exact chemical structure of the DSB. Microhomology-mediated end-joining (MMEJ), also called alternative end-joining (aEJ), involves limited end-processing to uncover short stretches (5–25 bp) of homology prior to ligation. Homologous recombination (HR, blue box) comprises a number of template-dependent pathways that exhibit high fidelity compared to SSA and NHEJ/MMEJ/aEJ. The HR pathways share the DNA strand invasion product, the 'D-loop,' but vary in the ensuing steps. The double Holliday junction (dHJ) pathway involves formation of the signature double Holliday junction intermediate, which can be resolved nucleolytically to generate crossover or noncrossover products. Alternatively, dHJs can be dissolved by the combined action of the BLM-TOPOIII α -RMI1-RMI2 complex (*Saccharomyces cerevisiae* Sgs1–Top3–Rmi1) to noncrossover products exclusively. The synthesis-dependent strand annealing (SDSA) pathway requires 'dissolution' of the 'D-loop' after extension by DNA polymerase and annealing of the extended strand with the second DSB end, leading exclusively to noncrossover products. During break-induced replication (BIR), 'D-loop' extension leads to DNA synthesis that copies the entire chromosome arm leading.

Sgs1–Top3–Rmi1 complex (human BLM-TOPOIII α -RMI1-RMI2; see [Table 1](#)) and the nuclease activity of the Dna2 helicase/nuclease ([Nimonkar et al., 2011](#)). The helicase activity of Sgs1 but not the catalytic activity of Top3 is required in this process ([Cejka et al., 2010a](#); [Niu et al., 2010](#)).

Rad51 Filament Assembly and Stability

The product of DSB resection is a 3'-OH ending ssDNA tail that allows assembly of the Rad51 nucleoprotein filament for

homology search and DNA strand invasion ([Figure 1](#), step 2; [Sung, 1994](#)). Binding of ATP endows Rad51 with a high-affinity DNA-binding state that allows its cooperative binding to ssDNA or double-stranded DNA (dsDNA). One Rad51 protomer binds 3–4 nucleotides, resulting in a right-handed Rad51 filament with a helical pitch of 130 Å and a 1.5-fold extension compared to B-form DNA ([Figure 1](#), step 2; [Conway et al., 2004](#)). Elegant X-ray crystallographic studies with RecA protein, the bacterial Rad51 homolog, showed nonuniform stretching of the DNA leaving triplets of normal B-form DNA

Figure 2 Replication fork support by homologous recombination (HR). A replication fork encountering a stalling lesion (black box) (step 1) may block the replicative helicase (step 2a) or the replicative DNA polymerase involving decoupling from the replicative helicase and generation of ssDNA gaps (step 2b). Multiple pathways, including homologous recombination, can engage under fork stalling conditions. The fork can be incised nucleolytically (step 3a) leading to a one-sided double strand break (DSB). Repair of a one-sided DSB by any end-joining pathway (NHEJ, MMEJ/aEJ) will result in a chromosomal rearrangement (step 4a), alternatively a telomere could be added leading to loss of the distal DNA (not shown). HR is the only pathway for accurate repair engaging the intact sister chromatid (step 4b) to restart replication (step 5a) after lesion removal (not shown). Uncoupled forks (step 2b) can engage at least three different DNA damage tolerance pathways to complete and/or restart replication. Replication fork reversal (step 3b) generates the so-called 'chicken-foot' intermediate, which provides an undamaged template for the blocked 3'-OH end (step 4c) leading the reestablishment of the replication fork (step 5b). Restart of DNA synthesis leaves a persisting gap (step 3c) that can be repaired by HR using two different pathways, depending on the specific mechanism (gap invasion, steps 4d, 5c; end invasion steps 4e, 5d). Alternatively, translesion synthesis (TLS) polymerases can directly synthesize across the blocking lesion (DNA synthesis marked in green) (step 3d) followed by switchback to the replicative polymerase for replication restart (step 4f). aEJ, alternative end-joining; NHEJ, non-homologous end-joining; MMEJ, microhomology-mediated end-joining.

flanked by large 8.4 Å gaps (Chen *et al.*, 2008). Presumably, this facilitates triplets to flip out during homology search suggesting that the fundamental search unit is a base triplet. Two challenges need to be addressed to target Rad51 to an ssDNA tail. First, ssDNA is avidly bound by RPA (replication protein A), the eukaryotic hetero-trimeric ssDNA-binding protein, which inhibits Rad51 filament formation. As detailed below, the recombination mediator proteins facilitate Rad51 filament nucleation on RPA-coated ssDNA (Liu *et al.*, 2011a). Second, Rad51 binds ssDNA only with slight preference over dsDNA. Given the vast excess of dsDNA over processed DSBs under typical DNA repair conditions, it is unclear how Rad51 is kept available for HR. Two potential solutions emanate: The dsDNA motor proteins Rad54 and Rdh4/Tid1 target dsDNA complexes of Rad51 or its meiotic homolog Dmc1 and dissociate Rad51 (or its meiotic homolog Dmc1) from dsDNA (Solinger *et al.*, 2002; Holzen *et al.*, 2006). Moreover, it is possible that Rad51 is kept available for repair by binding to specific protein factors to prevent duplex DNA binding, a scenario that has been proposed for BRCA2 and human RAD51 (Reuter *et al.*, 2014).

The role of RPA in HR is complex and multifaceted. RPA eliminates secondary structures in ssDNA to allow formation of productive Rad51-ssDNA filaments (Figure 1, step 1). In the absence of RPA, Rad51 also binds to secondary structures (dsDNA) resulting in Rad51-dsDNA filaments, which are incapable of homology search and DNA strand invasion. Hence the transition from RPA-coated ssDNA to Rad51-ssDNA filaments represents a critical quality control step. RPA also inhibits 3'-5' end resection by the Dna2 nuclease, an activity that would interfere with generating the 3' ssDNA tails needed for initiating HR (Cejka *et al.*, 2010a). During DNA strand invasion RPA binds the displaced strand in the 'D-loop' favoring heteroduplex DNA (hDNA) formation (Figure 1, step 3). Finally, there is evidence that RPA also binds the template strand within the 'D-loop' in front of the DNA polymerase extending the invading 3'-OH end to present a more optimal template for DNA synthesis, and therefore prevent polymerase stalling (Figure 1, step 4; Sneed *et al.*, 2013).

Recombination mediators permit stable Rad51 filament formation on RPA-coated ssDNA by facilitating nucleation of the Rad51 filament and/or stabilizing the Rad51-ssDNA

Figure 3 Interstrand cross-link (ICL) repair and homologous recombination. ICLs (black line connecting the Watson and Crick strand of the double helix) stall replication by blocking the replicative helicase (step 1). Fork incision of a unidirectional fork (step 2a) creates a one-sided double strand break (DSB) (step 3a) that liberates a 3'-end that can be resected for invasion of the homologous template (step 4a). After some synthesis, the replicative polymerase is blocked by the ICL and a nick is required to unhook the ICL (step 5a). This is followed by recruitment of a translesion synthesis (TLS) polymerase for lesion bypass (DNA synthesis shown in green) (step 6a) and the fork is reestablished with intact templates (step 7a) after removal of the ICL by nucleotide excision repair (NER) (not shown). Alternatively, dual incisions can unhook the damaged template (steps 1–2b) and generate a DSB including a short dsDNA gap (step 3b). First, DNA synthesis across lesion by TLS polymerases (DNA synthesis shown in green) establishes an intact template for DSB repair after removal of the ICL by excision repair (step 4b). DSB repair (steps 6b, 7b) is illustrated as an SDSA mechanism (see Figure 1).

filament from dissociation (Zelensky *et al.*, 2014). In yeast, Rad52 protein is the dominant mediator protein forming a multi-meric ring structure that binds ssDNA, Rad51, and RPA and facilitates the displacement of RPA by Rad51 on the ssDNA (Sung, 1997a). In mammals, the major mediator function is provided by the BRCA2 tumor suppressor protein (Jensen *et al.*, 2010), which explains why mutants or knock-downs of RAD52 in mammals elicit only modest phenotypes (Rijkers *et al.*, 1998; Feng *et al.*, 2010). The mechanism employed by both proteins is possibly different, as BRCA2, unlike Rad52, does not directly bind RPA (Jensen *et al.*, 2010). BRCA2 engages multiple strategies to favor formation of stable RAD51-ssDNA filaments by directly nucleating Rad51 filaments on RPA-coated ssDNA, impeding RAD51 binding to dsDNA and stabilizing the resulting filaments by reducing ATP turnover within the Rad51 filament (Liu *et al.*, 2010; Jensen *et al.*, 2010; Pellegrini *et al.*, 2002). Moreover, BRCA2 physically interacts with PALB2 and DSS1, both of which are required for HR (Table 1; Xia *et al.*, 2006; Gudmundsdottir *et al.*, 2004; Liu *et al.*, 2010). PALB2 localizes BRCA2 to sites of DNA damage (Xia *et al.*, 2006). The precise mechanism by which PALB2 and DSS1 promote HR through their interaction with BRCA2 is not well understood.

In addition to its role in promoting Rad51 filament formation on RPA-coated ssDNA, Rad52 plays a second role during HR in yeast and possibly also in humans. Yeast and human RAD52 are unique in their ability to mediate the annealing of complementary ssDNA that is fully coated by RPA, displaying specificity for the cognate RPA (Mortensen *et al.*, 1996; Sugiyama *et al.*, 1998; Grimme *et al.*, 2010). This reaction is critical for SSA (Figure 1) as well as for second end capture in the double Holliday junctions (dHJ) pathway (Figure 1, step 5a) and second end annealing in the synthesis-dependent strand annealing (SDSA) pathway (Figure 1, step 5b), as discussed in more detail below.

Another group of proteins implicated in the nucleation and stability of Rad51-ssDNA filaments are the Rad51 paralogs and their binding partners (Table 1; Liu *et al.*, 2011a). Budding yeast contains two protein complexes with Rad51 paralogs: the hetero-dimeric Rad55–Rad57 complex and the Shu complex consisting of two Rad51 paralogs, Psy3–Csm2, and their binding partners Shu1 and Shu2. Rad55 and Rad57 share the Walker A and B boxes with Rad51 enabling the hetero-dimer to bind and hydrolyze ATP. Rad55–Rad57 allows assembly of Rad51 filaments on RPA-coated ssDNA (Sung, 1997b). The homology of Psy3–Csm2 with Rad51 was only appreciated through the high-resolution crystal structure (Sasanuma *et al.*, 2013). These proteins lack ATP-binding motifs and the ability to bind or hydrolyze ATP. In humans, five RAD51 paralogs have been identified so far, but the sequence homology is insufficient to assign clear correspondence between XRCC2, XRCC3, RAD51B, RAD51C, or RAD51D with the yeast Rad51 paralogs (Liu *et al.*, 2011a). SWS1, a possible homolog of yeast Shu2, and its binding partner SWSAP1 associate with RAD51D in human cells. The Rad51 paralogs display distinct non-overlapping functions in Rad51 filament formation and/or stability, but their precise function is incompletely understood. The Rad55–Rad57 complex forms a co-filament with Rad51 possibly capping Rad51-ssDNA filaments and insulating them from disassembly by the Srs2 anti-recombinase

Table 1 Homologous recombination proteins in *Saccharomyces cerevisiae* and *Homo sapiens*

HR phase	Saccharomyces cerevisiae	Homo sapiens	Function
DSB processing	Dna2	DNA2	Nuclease/helicase
	Mre11–Rad50–Xrs2	MRE11–RAD50–NBS1	Nuclease, end-binding

Annual Review of Biochemistry 77, 229–257 and Symington, L.S., Rothstein, R., Lisby, M., 2014. Mechanisms and regulation of mitotic recombination in *Saccharomyces cerevisiae*. Genetics 198, 795–835.

(Liu *et al.*, 2011b). These data suggest that the structure of the Rad51-ssDNA filament conducting homology search and DNA strand invasion is considerably more complex than a simple homotypic filament of Rad51 protomers.

HOP2-MND1 is another mediator, forming a stable heterodimer required for HR in meiotic and mitotic cells in humans, whereas these proteins are meiosis-specific in yeast (Zierhut *et al.*, 2004). *hop2* knockout mice exhibit normal RAD51 and DMC1 (the meiosis-specific RAD51 paralog) foci formation; however, these foci persist much longer, suggesting that HOP2-MND1 act after filament assembly (Petukhova *et al.*, 2003).

RAD51-Associated Protein 1 (RAD51AP1, Table 1) physically interacts with RAD51 and DMC1, and is required for recombination in vertebrates but is not present in yeast. Depletion of RAD51AP1 does not affect the formation of RAD51 foci in human cells suggesting a function after filament assembly (Modesti *et al.*, 2007; Wiese *et al.*, 2007).

DNA Strand Invasion and Associated DNA Synthesis

Rad54 is a dsDNA motor protein functioning in conjunction with Rad51 during homology search and DNA strand invasion (Table 1; Figure 1, step 3; Petukhova *et al.*, 1998). Rad54

associates with and stabilizes the Rad51-ssDNA filament, which delivers Rad54 to the pairing site (Mazin *et al.*, 2000). In yeast, Rad54 is indispensable for 'D-loop' formation *in vitro* and the *in vivo* DNA repair phenotypes of *rad54* mutants are equal to those of *rad51* mutants (Petukhova *et al.*, 1998). In mammals, however, RAD51 is an essential gene, whereas RAD54 is not (Lim and Hasty, 1996; Essers *et al.*, 1997). This might be related to a role of mammalian RAD51 in stabilizing replication forks from degradation by MRE11, a function that is not shared with RAD54 (Schlachter *et al.*, 2011). Rad54 is a potent ATP-driven dsDNA translocase that disrupts dsDNA-Rad51 filaments (Solinger *et al.*, 2002). Importantly, during DNA strand invasion, Rad51 switches from binding the initial ssDNA to *hDNA*, i.e., duplex DNA (Figure 1, steps 2–3). Rad54 pumps the Rad51-bound duplex DNA to extend the nascent *hDNA* while simultaneously dissociating Rad51, thus allowing access of DNA polymerases to the invading 3'-end (Figure 1, steps 3–4; Wright and Heyer, 2014). Rad54 may play additional roles in remodeling nucleosomes during HR (Alexeev *et al.*, 2003). Rad54 paralogs in yeast (Rdh54) and humans (RAD54B) exert highly similar dsDNA-dependent ATPase activities exerting likely a similar, somewhat overlapping function in conjunction with Rad51 and Dmc1, the meiotic Rad51 paralog (Tanaka *et al.*, 2000; Holzen *et al.*, 2006).

Extension of the invading 3'-end in the nascent 'D-loop' by DNA polymerase (Figure 1, step 4) initiates recombination-associated DNA repair synthesis. The reaction is conceptually similar to leading strand synthesis during DNA replication but involves displacement of a contiguous DNA strand. Yeast and human DNA polymerase δ holoenzyme in conjunction with the PCNA (proliferating cell nuclear antigen) processivity clamp and the RFC (replication factor C) clamploader are highly capable of performing this specific type of DNA synthesis in reconstituted *in vitro* reactions (Li *et al.*, 2009; Sneed *et al.*, 2013; Wang *et al.*, 2004). Genetic evidence in yeast is consistent with the lagging strand DNA polymerase δ being the primary polymerase for first end DNA synthesis during HR (Li *et al.*, 2009; Sneed *et al.*, 2013; Wang *et al.*, 2004). It will be of interest to explore the potential contributions of other DNA polymerases, including translesion synthesis (TLS) polymerases, in D-loop extension.

The common core reactions of HR include DNA processing to produce ssDNA and the subsequent formation of the Rad51 nucleoprotein filament, which conducts homology search and DNA strand invasion. The resulting 'D-loop' contains the invading 3'-OH end, which primes HR-associated DNA repair synthesis, restoring sequence information lost at the break site. Processing of the extended 'D-loop' occurs in at least three distinct sub-pathways of HR, which determine the repair outcome of the event (Figure 1, after step 4), as discussed below.

Recombination and Double-Strand Break Repair

DSB repair is critical to maintain genome stability and can be achieved by three distinct pathways: End-joining, single-strand annealing (SSA), and HR (Figure 1). DNA end-joining, either the classic nonhomologous end-joining pathway (NHEJ) or the microhomology-mediated end-joining pathway (MMEJ), also called alternative end-joining (aEJ) in humans, requires no or minimal resection to restore contiguous chromosomes (Lieber, 2010). Depending on the exact chemical structure of the original DSB, end-joining is of variable fidelity but often involves deletions. SSA can occur when direct repeated DNA sequences flank the DSB. The process involves DSB resection, annealing of the repeated DNA sequences, flap-trimming, and gap repair by DNA synthesis and ligation to restore contiguous chromosomes. The process is inherently error-prone, deleting one repeat and the intervening sequence. The distinction between SSA, MMEJ, and NHEJ relates to different protein factors involved and the extent of homology ranging from > 25 bp for SSA to as little as 5 bp in MMEJ, whereas NHEJ processes ends with 0–4 bp homology.

The focus of this article is HR. The central HR reactions have been illustrated in the context of DSB repair in the preceding section up to the point, where the various HR sub-pathways diverge in the processing of the extended 'D-loop' (Figure 1, step 4). Below we discuss the ensuing steps.

Double Holliday Junction Formation, Resolution, and Dissolution

dHJ, a key intermediate in meiotic recombination, also occur during somatic DNA repair involving primarily sister

chromatids (Bzymek *et al.*, 2010). The displaced strand in the extended 'D-loop' captures the second end by DNA strand annealing involving Rad52 (Figure 1, step 5a) to generate a dHJ by DNA synthesis (Step 6a). It is unclear whether all strands are fully ligated before further processing. dHJs can be resolved by structure-selective DNA endonucleases into 'crossover' and 'noncrossover' products (steps 7a–8a, 7b–8b). A candidate protein is Yen1 (human GEN1, Table 1), a nuclease that is capable of resolving Holliday junctions (HJs) with fully ligated strands (Matos *et al.*, 2011). Yen1 is activated in the cell cycle just around the time of chromosome segregation in anaphase, and likely represents a failsafe mechanism of unresolved joint molecules. Yen1 mutants do not display an overt HR phenotype in otherwise wild type cells. In contrast to Yen1/GEN1, the structure-selective endonuclease Mus81–Mms4 is very inefficient in cleaving HJs or dHJs when all strands are ligated, suggesting that it cleaves earlier intermediates before ligation (Ehmsen and Heyer, 2008). Mutants in the Mus81–Mms4 complex show defects in 'crossover' formation in somatic DSB repair, confirming the involvement of this endonuclease in HR (Ho *et al.*, 2010). Slx1–Slx4, another structure-selective nuclease, appears to play no obvious role in HR in budding yeast, based on the mutant phenotype, but has been implicated in HJ/dHJ processing in mammalian cells (Fricke and Brill, 2003; Castor *et al.*, 2013). Seminal work with the human BLM–TOPOIII α –RMI1 uncovered a novel mechanism to process dHJs by a mechanism termed dissolution (Wu and Hickson, 2003). The significance is that dHJ dissolution leads only to 'noncrossover' outcome. This mechanism provides a satisfying interpretation for the hyper-sister chromatid exchange phenotype of BLM-deficient human cells as an inability to dissolve dHJs, which instead give rise to 'crossovers' by resolution. dHJ dissolution is mechanistically complex and requires the coordinate movement of both HJs in the dHJ toward each other by the BLM helicase (step 7c). The topological stress accumulating between the two individual HJs is addressed by TOPOIII α and its RMI1 cofactor. The final hemi-catenane intermediate (step 8c) is an excellent substrate for decatenation by Top3–Rmi1 (Cejka *et al.*, 2010b). The role of the RMI2 cofactor in mammals remains to be determined. The structure and mechanism of the BLM–TOPOIII α –RMI1 complex is highly conserved in eukaryotes (Table 1), and it is possible that this complex also targets other HR-dependent joint molecules for dissolution.

Synthesis-Dependent Strand Annealing

SDSA involves alternative processing of the extended 'D-loop' by dissolution and annealing of the newly synthesized strand with the ssDNA tail of the second end of the frank (two-sided) DSB (Figure 1, step 5b). The candidate proteins for dissolution of the extended D-loop are listed in Table 2 and discussed later. The annealing step is likely catalyzed by Rad52, the protein capable of annealing complementary ssDNA fully coated by RPA. DNA synthesis and ligation are required to restore contiguous chromosomes. The DNA synthesis (step 6b), as well as DNA synthesis from the second end in the dHJ sub-pathway (step 6a) is simpler than extension of the first end in the 'D-loop' as no displacement synthesis is involved. It is presently unclear which DNA polymerases are involved in

Table 2 Homologous recombination proteins in *Saccharomyces cerevisiae* and *Homo sapiens* with anti-recombination and anti-crossover functions

HR role	<i>Saccharomyces cerevisiae</i>	<i>Homo sapiens</i>	Function
Anti-rec	Srs2	FBH1, PARI BLM, RECQ5	Dissociation Rad51-ssDNA filament
	Sgs1	FANCI	Dissociation of nascent D-loop
	Top3-Rmi1	BLM TOPOIII α -RMI1-RMI2	
Anti-crossover	Srs2	BLM, RECQ1 RTEL1	Dissociation of extended D-loop
	Mph1	FANCM	dHJ dissolution
	Sgs1-Top3-Rmi1	BLM-TOPOIII α -RMI1-RMI2	

Note: Antirecombination (Anti-rec) refers to activities that lead to an overall decrease in recombination repair products. Anti-crossover refers to activities that specifically block formation of crossover products.

Source: Modified from Heyer, W.D., Ehmsen, K.T., Liu, J., 2010. Regulation of homologous recombination in eukaryotes. Annual Review of Genetics 44, 113–139.

this step. Importantly, SDSA always leads to a ‘noncrossover’ outcome of DSB repair.

Break-Induced Replication

Break-induced replication (BIR) engages the core mechanism of HR to establish a noncanonical replication structure that copies the entire chromosome arm in the absence of a second DSB end in a conservative manner (Figure 1, steps 5c–6c; Malkova *et al.*, 1996). BIR is formally analogous to one-sided DSB repair, but BIR may occur outside the S phase context emblematic for one-sided DSB repair (Figure 2). BIR has also been invoked as the conceptual mechanism for the alternative lengthening of telomeres (ALT) in cancer cells to maintain telomeres in the absence of telomerase. It is presently unclear what distinguishes BIR from the other HR sub-pathways, in particular how the absence of the second end can be sensed. While BIR can copy an entire chromosome arm involving the components of a regular replication fork, the associated DNA synthesis is significantly more error-prone than DNA replication (Malkova and Haber, 2012). BIR leads to loss-of-heterozygosity distal to the DSB site when using the homologous chromosomes as a template, or to nonreciprocal translocations when copying from a nonallelic locus.

HR achieves high-fidelity repair of DSBs in comparison to alternative mechanisms such as SSA, NHEJ, or MMEJ. However, the DSB repair by HR is not error-free and a 1000-fold elevation in mutation frequencies close to DSBs repaired by HR have been recorded with even larger mutagenic increases in BIR-mediated events (Malkova and Haber, 2012). Foremost, dispersed repeats present throughout genomes provide opportunity for nonallelic recombination, with the potential to generate large-scale chromosomal rearrangements.

Recombination and DNA Replication

Replication of DNA is central to life and tightly regulated to ensure genomic stability. Changes to the nucleotide pools or DNA lesions may lead to stalling of the replicative DNA polymerases and/or replicative helicase (Figure 2). Even in the

absence of DNA damage, repetitive DNA elements, DNA secondary structures, transcription complexes, RNA–DNA hybrids, and fragile sites can lead to slowing or stalling of DNA replication (Zeman and Cimprich, 2014). Figure 2 illustrates how HR serves as a repair or tolerance mechanism in the recovery of stalled or broken replication forks.

Multiple HR, fork remodeling, and TLS factors are involved in the recovery of stalled replication forks. Stalled replication forks can be cleaved, resulting in a one-sided DSB to initiate HR using the sister chromatid as a template (Figure 2, steps 2a, 3a, 4b, 5a). Repair of one-sided DSBs by HR is crucial, as events mediated by any end-joining pathway would result in associated chromosomal rearrangements (Figure 2, step 4a; Pace *et al.*, 2010; Adamo *et al.*, 2010). Upon prolonged replication stress and fork stalling by extended hydroxyurea (HU) or camptothecin (CPT) treatment (Hanada *et al.*, 2007; Regairaz *et al.*, 2011) cells accumulate DSBs in a Mus81–Mms4/EME1-dependent fashion. These DSBs likely reflect direct cleavage of the stalled fork by Mus81–Mms4/EME1, as DNA substrates mimicking stalled replication forks are among the best substrates for its endonuclease activity (Ehmsen and Heyer, 2008; Ciccio *et al.*, 2003). In all organisms tested, cells lacking *MUS81* or *EME1* orthologs are sensitive to replication blocking agents, but not IR which causes frank (two-sided) DSBs (Dendouga *et al.*, 2005; Ciccio *et al.*, 2008). ‘Resolution’ of a single HJ intermediate that arises in the process is necessary before chromosome segregation (Figure 2, steps 4a–5a).

Alternatively, DNA damage may be tolerated instead of repaired to ensure completion of DNA replication and hence survival (Figure 2). When the 3′ end of the leading strand is blocked, fork regression can cause a template switch to the nascent sister chromatid, forming the chicken-foot intermediate which is analogous to an HJ (Figure 2, steps 3b). Direct visualization provided evidence for reversed forks in checkpoint-proficient mammalian cells after exposure to sublethal doses of topoisomerase 1 inhibitors, camptothecin, and topotecan (Chaudhuri *et al.*, 2012). DNA synthesis on the sister chromatid (step 4c) allows bypass of the lesion after reversing the chicken-foot structure (step 5b). Several potential factors have been identified, including the DNA motor proteins Rad5/HLTF, FANCM, SMARCA1, and ZRANB3 that may

be involved in fork and/or chicken-foot reversal (Zeman and Cimprich, 2014). This mechanism is likely independent of RAD51 as no DNA strand invasion is required, but RAD52-mediated strand annealing may be involved.

DNA lesions that block leading or lagging strand synthesis can be tolerated through S phase by gap repair (Figure 2, steps 3c; Zeman and Cimprich, 2014) (Note that Figure 2 only represents leading strand blockage but the following mechanisms described can also occur if there is a lagging strand block.). Gap repair can ensue in two ways. During gap invasion, the uninterrupted strand forms a Rad51 filament to invade the intact sister chromatid (steps 4d, 5c). Following joint migration, the displaced strand of the joint molecule serves as the template for DNA synthesis. Since the invading DNA strand has no free ends, this type of DNA strand invasion poses specific topological problems. Alternatively, during end invasion the leading strand can invade the sister chromatid template for DNA synthesis past the lesion (step 4e). End invasion requires a helicase to generate a ssDNA template for Rad51 filament assembly. The gap is closed after withdrawal of the newly synthesized strand (step 5d), analogous to SDSA (Figure 1). Inherent in the depiction of gap repair in Figure 2 is restart of leading strand and lagging strand (not shown) replication. While restart of lagging strand replication is considered intrinsic to regular DNA synthesis, it has only been recently realized that also restart of leading strand replication is common (Lopes *et al.*, 2006).

Finally, lesions blocking the replicative DNA polymerases can be bypassed by a polymerase switch to TLS polymerases (Figure 2, steps 3d, 4f; Goodman and Woodgate, 2013). These specialized low fidelity DNA polymerases lack proofreading activity and contain enlarged active sites to accommodate damaged bases. Bypass is likely achieved by a combination of specialized TLS polymerases that have the ability to add a base opposite the damaged template and other TLS polymerases than can extend the unusual primer template structure before switching back to the replicative polymerase (Prakash and Prakash, 2002).

Pathway choice at stalled replication forks is an important issue and posttranslational modification of the processivity clamp PCNA serves as the nexus to regulate fork regression, HR-mediated template-switch, and translesion DNA synthesis (Moldovan *et al.*, 2007). Mono-ubiquitylation of K164 on PCNA promotes DNA polymerase switching from replicative DNA polymerases to TLS polymerases, which have, in addition to a PCNA-interacting motif, a distinct ubiquitin-interaction motif that enhances their affinity to ubiquitylated PCNA. Switchback to replicative DNA polymerases may involve deubiquitylation or unloading of modified PCNA. Poly-ubiquitylation of K164 on PCNA involving K63-linked ubiquitin chains favors fork regression, potentially by providing a specific binding site for fork regression motors such as ZRANB3. Instead, sumoylation of the same K164 residue on PCNA recruits the anti-recombinogenic helicase Srs2 that dissociates Rad51 from ssDNA and effectively inhibits HR (see below, Table 2).

Processing of replication forks and collisions of replication forks with active transcription complexes (see Aguilera and Garcia-Muse, 2013) are a major source of genomic instability. HR competes with TLS and fork regression to process stalled

forks or complete DNA replication by gap repair to suppress genomic rearrangements and enable complete and faithful replication of the genome.

Recombination and Interstrand Cross-Link Repair

DNA ICLs are cytotoxic lesions that covalently link the Watson and Crick strands of duplex DNA effectively blocking replication and transcription. Exogenous ICL-inducing agents include nitrogen mustards, psoralens, mitomycin C, and platinum-like cisplatin that are utilized as anticancer therapeutics (Deans and West, 2011). Nitrous acids that form as by-products of nitrite metabolism and aldehydes from alcohol or fat metabolism are endogenous sources of ICLs (Deans and West, 2011; Langevin *et al.*, 2011). Figure 3 illustrates two models for how HR participates in the repair of ICLs initiated by stalling of one or two converging replication forks.

Sensitivity to ICL agents is a hallmark of cells lacking the Fanconi anemia (FA) pathway. FA is a rare genetic disorder that is characterized by childhood onset of aplastic anemia, bone marrow failure, cancer, and leukemia susceptibility, and cellular hypersensitivity to ICL agents (Kim and D'Andrea, 2012). Cells derived from FA patients show increased chromosome breakage and radial chromosomes after exposure to ICL-inducing agents, likely because DSBs left unrepaired can fuse with other chromosome arms through NHEJ (Figure 2, step 4a). The FA pathway may function to actively stabilize the replication fork to allow for HR-mediated repair and suppress NHEJ to decrease genomic instability (Pace *et al.*, 2010; Adamo *et al.*, 2010).

To date, identification of 17 FA genes has increased the molecular understanding of this disease (Wang and Smogorzewska, 2015). Eight proteins (FANCA, B, C, E, F, G, L, and FANCM/FAAP24) form the FA core complex that is responsible for recognizing a cross-link in DNA. FANCM is an ATPase and translocase that is essential for recognizing the ICL at the stalled replication fork, recruiting the FA core complex to the covalently linked duplex DNA. FANCD2 and FANCI are mono-ubiquitylated by FANCL and this serves as a reversible signal that causes these proteins to localize to DNA damage. The other FANCA genes encode proteins factors that appear to be more involved in the ensuing DNA transactions (Deans and West, 2011). FANCI/BRIP1 is a helicase and ATPase that has been shown to bind to BRCA1 (FANCS), another important factor involved in genomic stability. FANCD1 is identical to BRCA2, the central HR mediator protein in mammals described above (Howlett *et al.*, 2002). The BRCA2-interacting partner PALB2 was identified as FANCN, whereas the RAD51C protein as FANCO. These findings suggest that possibly additional HR proteins (see Table 2) might be involved in FA, as the recent identification of the HR nuclease scaffold protein SLX4 as FANCP has already shown (Kim *et al.*, 2011).

ICLs are most directly recognized genome-wide during S phase because they stall replication forks, as illustrated in Figure 3. The FA core complex recognizes ICLs that stall replication forks and signals downstream repair factors including the aforementioned FANCA proteins that act on DNA. Stalling of transcription complexes offers an alternative pathway of ICL recognition, independent of DNA replication. In S phase, ICL

repair is initiated by ubiquitylated FANCI–FANCD2 and involves factors from Nucleotide Excision Repair (NER), HR, and TLS DNA polymerases. DSBs have been identified as a major reaction intermediate and substrate for HR during ICL repair (Figure 3; Long *et al.*, 2011; Knipscheer *et al.*, 2009). A replication fork approaching an ICL from one side, for example near the telomere or in mid/early S phase, leads to a one-sided DSB after cleavage of the stalled fork, which can be repaired by HR. Resection of the DSB permits RAD51 filament formation for invasion of the intact sister to create a ‘D-loop’ (Figure 3, steps 3a, 4a). After the initial extension at the ‘D-loop,’ an additional nick on the other side of the ICL unhooks the damaged base (step 5a). A polymerase switch to a TLS polymerase to synthesize across the lesions and subsequent excision of the lesion by NER (Figure 3, step 6a) restores the chromosome potentially leading to reestablishment of the replication fork (Figure 3, step 7a; Deans and West, 2011; Zhang and Walter, 2014).

The mechanism of repair of an ICL flanked by two converging replication forks, as for example in late S phase, has been elucidated in an elegant system using cell-free *Xenopus laevis* egg extracts and a plasmid substrate with a single site-specific ICL. When the replicative polymerase encounters the ICL, leading strand synthesis stalls 20–40 nt away from the ICL (Figure 3, step 2b; Raschle *et al.*, 2008). After replisome remodeling, successive nicks on either side of the ICL unhook the damaged template (step 3b) and a polymerase switch recruits TLS polymerases (step 4b). Although the specificity and molecular mechanism of recruitment of the low fidelity DNA polymerase is not well understood, REV1–REV3–REV7 (REV1–Pol ζ) is a candidate complex (Kim and D’Andrea, 2012). The initial synthesis up to one nucleotide from the ICL (step 3b) is followed by synthesis across the lesion (steps 4b). NER removes the ICL (step 5b), restoring a proper template for DSB repair by HR (steps 6b, 7b; Raschle *et al.*, 2008).

Six nucleases with varying substrate specificity for joint molecule DNA substrates have been implicated in processing ICLs because mutations in corresponding genes increase sensitivity to ICL agents (Zhang and Walter, 2014; Kim and D’Andrea, 2012; Deans and West, 2011). SNM1A and SNM1B are exonucleases that may function downstream of the incisions instead of unhooking. Another nuclease, FAN1, was identified by its interaction with FANCD2 but the physiological relevance is unclear, as *FAN1* deficiency does not lead to an FA-like phenotype. MUS81–EME1 and SLX1 cleave nicked DNA joint molecules that could arise when a replication fork encounters an ICL; however, even though human MUS81–EME1 or SLX1 patients have not been described, deficiency of animal models in either endonuclease does not phenocopy FA (Dendouga *et al.*, 2005; Castor *et al.*, 2013). These endonucleases may have partially overlapping roles in ICL repair. Lastly, mutations in the endonuclease XPF (FANCD2)–ERCC1 lead to FA, and XPF–ERCC1 have been shown to unhook ICLs *in vivo* and *in vitro* (Zhang and Walter, 2014). Intriguingly, the SLX4 (FANCD2) scaffold protein interacts with XPF–ERCC1, MUS81–EME1, as well as SLX1, and SLX4 deficiency causes FA (Fekairi *et al.*, 2009). This raises the possibility that all three nucleases could be recruited to the ICL for unhooking to allow for repair of the damaged template. It is unclear what role FANCD2 plays in this context and whether

its ability to dissociate RAD51 from ssDNA is important for ICL repair.

Taken together, the FA pathway shows extraordinary complexity as it detects ICLs in replicating cells and coordinates the interplay between HR, certain NER factors, and TLS polymerases to repair ICLs and suppress chromosomal rearrangements induced by NHEJ.

Pathway Regulation and Crossover Control

Several layers of regulation operate throughout the HR pathway targeting multiple proteins and DNA intermediates. The sister chromatid is the preferred template, and HR is largely limited to the S and G2 phases of the cell cycle. The major control step to limit HR during DSB repair in the G1 phase of the cell cycle is to regulate DSB end resection involving the cyclin-dependent kinases targeting Sae2/CtIP, elaborate histone modifications, and the mammalian 53BP1 protein (Daley and Sung, 2014; Symington and Gautier, 2011). Inhibition of DSB resection favors end-joining pathways (Figure 1), which involve no or little end resection.

An additional target of regulation is the Rad51–ssDNA filament (Figure 1, steps 2 to 1). Seminal work on the budding yeast anti-recombinase Srs2 established a mechanism, by which Srs2 translocates on ssDNA to dissociate Rad51–ssDNA filaments (Table 2; Veaute *et al.*, 2003; Krejci *et al.*, 2003). Four motor proteins, FBH1, BLM, RECQ5, and FANCD2, as well as a non-motor protein, PARI, have been postulated to exert this function in mammalian cells (Table 2). The diversity of anti-recombinases may suggest functional specialization as well as cooperation between motor proteins and PARI, which lacks a motor domain and may target motor proteins to RAD51. Rad51 filament dissociation by Srs2 is regulated by Rad51 paralogs in *Saccharomyces cerevisiae* (Liu *et al.*, 2011b), and the mammalian RAD51 paralogs may play similar roles.

A final tier of HR regulation dissociates the nascent ‘D-loops’ (Figure 1, steps 3 to 2), a process that has been called heteroduplex rejection (Hombauer *et al.*, 2011). This quality control mechanism employs components of the mismatch repair pathway and the Sgs1–Top3–Rmi1 complex to abort DNA strand invasions, where the template is not fully homologous with the invading DNA to prevent recombination between nonallelic sites (Table 2). The exact mechanism still needs to be established, but in order to be biologically effective as an anti-recombination mechanism, heteroduplex rejection should engage before DNA polymerase extends the ‘D-loop’ (Figure 1). In sum, HR is regulated during at least three distinct phases, DSB end resection, Rad51 filament, and the nascent ‘D-loop’ to ensure proper DSB repair pathway choice and enforce quality control.

HR can result in ‘crossover,’ the reciprocal exchange of chromosome arms flanking the event, which manifest themselves as sister chromatid exchanges during somatic DNA repair. In this context, ‘crossovers’ are actively avoided by at least two distinct mechanisms (Table 2). As discussed above, the BLM–TOPO3 α –RMI1 (yeast Sgs1–Top3–Rmi1) complex dissolves dHJ (Figure 1, steps 7c, 8c; Table 2) as a mechanism to finalize HR events as ‘noncrossover’ events (Wu and Hickson, 2003; Cejka *et al.*, 2010b). A second ‘anti-crossover’ mechanism

is represented by the SDSA sub-pathway of HR (Figure 1, steps 5b, 6b). Dissociation of the 'D-loop' after extension by DNA polymerases leads to reannealing of the newly synthesized strand with the second DSB end, which was not involved in the DNA strand invasion. A number of motor proteins, Srs2 and Mph1 in yeast, as well as BLM, RECQ1, FANCM, RTEL1 in mammals have been shown or suggested to dissolve 'D-loops' *in vitro* and postulated to do so in cells (see Table 2 and Further Reading). Genetic data are consistent with an anti-crossover role for these proteins, although in the case of BLM, dHJ dissolution may be the primary mechanism involved. The removal of Rad51 on the second end to allow annealing may be an additional requirement for SDSA. The specificity of the various motor proteins for a specific 'D-loop' structure (nascent or extended), in particular their relationship to 'D-loops' being extended by DNA polymerase, still needs to be established.

In conclusion, while meiotic recombination is geared to generate 'crossovers' that physically connect the two homologous chromosomes during chromosome segregation, HR during somatic DNA repair engages at least two distinct mechanisms to actively avoid 'crossover' formation between participating sister chromatids.

HR and Human Disease

Maintaining genomic stability plays a pivotal role in preventing human disease (Moynahan and Jasin, 2010). The human tumor suppressor protein BRCA2 illustrates most strikingly the connection between HR, human disease, and cancer (Moynahan *et al.*, 2001). The molecular function of BRCA2 is best understood as a mediator protein to nucleate Rad51 filaments, as discussed above. Rad51 filaments protect stalled forks from degradation by MRE11 and also perform homology search and DNA strand invasion during HR (Schlachter *et al.*, 2011; Jensen *et al.*, 2010). Both aspects may be distinct functions to maintain genomic stability. Bi-allelic mutations in BRCA2 cause FA (Howlett *et al.*, 2002), a complex human syndrome discussed more in detail above. Heterozygous BRCA2 mutants carry a greatly enhanced risk for cancer, especially for breast and ovarian cancer. Consistently, the BRCA2-interacting protein PALB2 has also been identified as a FANCD1 gene (FANCD1) and tumor suppressor (Reid *et al.*, 2007). Considering our knowledge of the HR pathway (Figure 1), more candidate genes may be involved at the nexus of HR, human disease and cancer, as already recognized for the RAD51 paralogs RAD51B/C/D, SLX4, and BLM (see Table 1).

HR has dual significance for cancer. As discussed above, the involvement of HR in the etiology of cancer is well documented (Moynahan and Jasin, 2010). In addition, HR addresses many types of DNA damage induced by current modalities of anticancer therapy. These include DSBs induced directly by ionizing radiation or drugs as well as indirectly by targeting topoisomerase II, topoisomerase I-targeted drugs, ICL-inducing drugs, as well as drugs interfering directly or indirectly with DNA replication. This offers the prospect of exploiting genetic or pharmacological approaches to disable HR to sensitize tumor cells to such DNA damage-based therapies (Powell and Bindra, 2009; Carvalho and Kanaar, 2014). Pioneering work with BRCA-deficient cells and tumors

exploits the synthetic lethality between an HR-defect and inhibition of the poly-ADP ribose polymerase (PARP) as a strategy to treat HR-deficient cancers (Bryant *et al.*, 2005; Farmer *et al.*, 2005). These exciting developments have given the HR field an additional purpose.

Conclusions

- HR comprises a web of interrelated pathways supporting genomic stability through their function to repair or tolerate DNA damage.
- HR is highly regulated to avoid recombination in the G1 phase of the cell cycle and revert inappropriate formation of Rad51-ssDNA filaments or DNA strand invasions.
- The full extent of the involvement of HR genes in cancer predisposition and possibly other human diseases still needs to be established.
- The role of HR in DNA damage-based modalities of cancer treatment is beginning to be appreciated and therapeutically exploited.

Glossary

Nontemplate strand DNA strand that is same sequence as transcribed RNA, the 'top' strand.

Operator A DNA sequence bound by a repressor or activator.

Promoter DNA sequence recognized by RNA polymerase that sets the start site for transcription.

Ribonucleoside triphosphates (rNTPs) rNTPs used by RNA polymerase to synthesize RNA.

Template strand DNA strand that is complementary to transcribed RNA, the 'bottom' strand.

Introduction

Transcription, the synthesis of a 5'→3' RNA chain complementary to a DNA template, is the first step in the expression of a gene. Consequently, the control of transcription is fundamentally important to all organisms. In all three kingdoms of life, RNA synthesis is catalyzed by multi-subunit DNA-dependent RNA polymerases, which generate RNA through the hydrolysis of pyrophosphate from ribonucleoside triphosphates (rNTPs). In this process, RNA polymerase (RNAP) first binds to a specific DNA sequence (a promoter) that sets the start site for transcription. RNAP then starts RNA synthesis (initiation), proceeds to transcribe through the gene(s) (elongation), and finally stops transcription at a specific site (termination). Additional factors can control the process by interacting with the polymerase, the DNA, or the RNA, which in turn affects the various steps. Thus, a myriad of outcomes arising from these various interactions results in the sophisticated regulation needed for the proper growth and development of a cell and for the cell to adapt to various environmental stresses.

Despite their seeming simplicity, prokaryotes (bacteria and archaea) have elegant mechanisms to perform and regulate the process of transcription. Because prokaryotes not only survive but flourish in a wide range of environments, one might surmise that the process of transcription varies widely among prokaryotes and between the prokaryotic and eukaryotic

worlds. However, fundamental mechanisms underlie how transcription is done throughout biology. In this article we will review this process in prokaryotes and also indicate some of the basic similarities among all organisms (reviewed in [Decker and Hinton, 2013](#)).

Core RNA Polymerase

RNA polymerase 'core' is the RNA-synthesizing machine. In bacteria it is composed of 5 subunits: β , β' (the two largest proteins), two α 's, and ω ([Figure 1\(a\)](#), left; [Zhang *et al.*, 1999](#); reviewed in [Murakami and Darst, 2003](#)). Although archaeal core ([Figure 1\(a\)](#), right) and eukaryotic cores (for Pol I, Pol II, and Pol III) are composed of more subunits, they too contain proteins that are homologous to these bacterial proteins ([Hirata *et al.*, 2008](#); reviewed in [Vannini and Cramer, 2012](#); [Ebright, 2000](#); [Jun *et al.*, 2011](#)). All cores are arranged like a 'claw' with the active site and a catalytic Mg^{++} located at the center. The largest subunits, such as β and β' in bacteria, generate the top and bottom 'pincers' of the claw with a long alpha helix within β' (or its equivalent in archaeal or eukaryotic core) extending from the top to the bottom. This is the β' bridge helix (shown as red helix in [Figure 1\(a\)](#)).

Bacterial core is assembled as: $\alpha_2 + \beta + \beta' / \omega$. Each α subunit is composed of an N-terminal domain (NTD) tethered to its C-

Figure 1 Structures of bacterial and archaeal RNA polymerases and Regions of σ^{70} . (a) RNA polymerase core of *E. coli* (Murakami, 2013; PDB: 4IGC without the σ subunit; left) and *Sulfolobus solfataricus* (Hirata *et al.*, 2008; PDB: 2PMZ; right). Homologous subunits in the bacterial and archaeal cores are colored similarly as follows: β' , A/A', dark blue (except for the bridge helix); β , B, light blue; α_1 , D, dark green; α_2 , L, light green; ω , K, magenta. The β' bridge helix is shown in red; the Mg^{++} at the active site is the red sphere. Only one of the α CTDs (α_1 CTD) can be seen in the *E. coli* structure. Archaeal subunits E', F, H, N, and P that are missing in bacteria are shown in black. (b) *E. coli* RNA polymerase holoenzyme (Murakami, 2013; PDB: 4IGC). The σ^{70} subunit is shown in yellow and the positions of the 4 major Regions (1, 2, 3, and 4), the nonconserved region (NCR), and subregion 3.2 are indicated. (c) Regions and subregions of σ^{70} . Important interactions between σ^{70} and promoter DNA or core are shown on the top or bottom, respectively.

terminal domain (CTD) by a flexible peptide linker. (Only the CTD of α_1 is observed in the structure in Figure 1(a).) Dimerization of the two α 's occurs through their NTDs. As each NTD also interacts with either β or β' , the two α subunits are distinguished within core by their interaction with the particular large subunit. ω , the smallest subunit, serves as a chaperone for β' (Mathew and Chatterji, 2006; and references therein) and when present in core, generates part of the binding site for the small molecule effector ppGpp, which is

involved in the ability of some bacteria, such as *Escherichia coli*, to respond to limiting nutrient conditions (Mechold *et al.*, 2013; Zuo *et al.*, 2013).

Bacterial RNA Polymerase Holoenzyme

Besides the RNA-synthesizing core, RNA polymerases also require a specificity factor to recognize DNA promoter sequences

Figure 2 The process of transcription in bacteria. (1) Core polymerase. Schematic of core based on structural information (Figure 1(a)). Positions of the α CTDs, β -flap, β' -CH (clamp helix), downstream DNA channel, and active site are shown. (2) Holoenzyme. σ is shown in yellow; core is shown in cyan. Positions of σ Regions 1.1, 2, 3, 3.2, and 4 are indicated. (3) Closed complex (RPc). Promoter DNA lies across the face of RNAP. Positions of promoter elements (UP, -35, -15 TG $^{-14}$, and -10) are indicated. (4) Open complex (RPo). Isomerization of RNAP and bending, unwinding of the DNA generates the transcription bubble surrounding the start site and the β' clamp, which secures the DNA within the downstream DNA channel. (5) Initiating complex (RPi). The presence of rNTPs, which enter through the secondary channel, starts RNA synthesis. The initially transcribed RNA remains annealed to the DNA template, creating a RNA/DNA hybrid of 8–9 bp. (6) Scrunched complex. As RNA is made, RNAP moves forward pulling the DNA into the active site but without releasing the promoter. The release of small abortive transcripts collapses the scrunch returning the complex back to RPo. (7) Elongating complex (EC). RNA exits through the RNA exit channel, which displaces σ Regions 3.2 and 4, eventually resulting in the loss of σ . (8) Elongation factors NusA and NusG. NusA interacts with the β -flap, α CTD, and RNA. NusG interacts with the β' -CH, extending over the DNA upstream of the transcription bubble to hold the DNA even more securely. (9) Termination. The RNAP/DNA/RNA complex is disrupted by the presence of a terminating hairpin (intrinsic) or a hexamer of Rho protein (Rho-dependent).

that set the start site for transcription. In bacteria, these factors are the σ subunits (reviewed in Gruber and Gross, 2003). The combination of core with σ constitutes the holoenzyme. All

bacteria have a primary ('housekeeping') σ , such as σ^{70} of *E. coli*, that is needed to transcribe genes during exponential growth (Figure 1(b) shows the structure of *E. coli* σ^{70}).

containing holoenzyme with σ in yellow (Murakami, 2013).). In addition, most bacteria have a few to dozens of σ factors that are used during other growth conditions or times of stress (reviewed in Osterberg *et al.*, 2011). Primary σ 's contain 4 broad regions of sequence similarities (Regions 1, 2, 3, and 4) with subregions (1.1, 1.2, 2.1, 2.2, etc.) identified by sequence, structure, and function (Figures 1(b) and 1(c)). Primary σ factors also can contain a nonconserved region (NCR) between Regions 1 and 2. Alternate σ 's fall into two categories: those related to σ^{70} and those of the disparate σ^{54} family. Within the σ^{70} family, one category of alternate σ 's is quite similar to primary σ factors, retaining similarities within Regions 2, 3, and 4. The other class, extracytoplasmic (ECF) σ 's, are less similar, only having recognizable Regions 2 and 4. ECF σ 's are involved in processes concerning cell surface or transport as well as other cellular needs. The σ^{54} family represents a separate class of factors that are not related to the σ^{70} family members.

Extensive interactions between core and σ secure σ within the holoenzyme (Figure 1(b); Vassilyev *et al.*, 2002; Murakami *et al.*, 2002b; Murakami, 2013; reviewed in Decker and Hinton, 2013). Within the σ^{70} family there are three primary contacts: σ Regions 2.1 and 2.2 with the β' clamp helix (CH), a coiled-coil motif; the C-terminal portion of σ (Regions 4.1/4.2/H5) with a portion of β called the β -flap; and σ Region 3.2 with the RNA exit channel, a portion of β and β' that will provide the path for the emerging RNA during transcription (Figures 1(b) and 1(c); shown schematically in Figure 2, steps 2 and 6). Although the ECF σ 's lack a homologous Region 3, presumably they too have residues that make interactions that are similar to those between Region 3.2 and core. In addition, crosslinking analyses suggest that like σ^{70} , the disparate σ^{54} family members also have interactions with the β' CH and the β -flap (reviewed in Wigneshweraraj *et al.*, 2008). Finally, primary σ factors have an additional interaction made by Region 1.1 and the β , β' – cleft the portion of core that will hold the DNA downstream of the transcription start site once the promoter is stably bound (Decker and Hinton, 2013; Murakami, 2013; Bae *et al.*, 2013). Thus, Region 1.1, with its abundance of negatively charged residues, is thought to provide a 'placeholder' in the absence of the DNA.

The Process of Transcription in Bacteria

Initiation

Transcription is a highly ordered process. A detailed understanding of bacterial transcription at a molecular level has been obtained from decades of extensive genetic and biochemical analyses together with more recent structures of bacterial and eukaryotic polymerases with and without DNA and RNA (reviewed in Saecker *et al.*, 2011; Hook-Barnard and Hinton, 2007; Decker and Hinton, 2013). This article focuses on *E. coli* σ^{70} -containing RNAP since most biochemical analyses have used this polymerase as the model. However, it should be noted that there are differences depending on the particular σ factor and the particular bacterium.

Transcription initiation begins with the recognition of double-stranded promoter elements: σ Region 4 and the – 35

element ($^{-35}\text{TTGACA}^{-30}$), σ Region 3.0 and the extended – 10 ($^{-15}\text{TG}^{-14}$), σ Region 2.4 and the first bp of the – 10 element (^{-12}T), and the α CTDs and A/T-rich sequences called UP elements (– 40 to – 60) (Figure 1(c) and Figure 2, step 3). Because σ by itself binds extremely poorly to DNA, this recognition and binding occurs only within the context of the holoenzyme. The positions indicated for the elements represent the ideal, but there is limited flexibility. For example, the spacing between the 3' end of the – 35 element (typically position – 30) and the start of the – 10 element (typically position – 12) can vary from 16 to 18 bp. In addition, at the very strong ribosomal promoters (detailed below), the – 10 element actually occurs from – 9 to – 14.

As promoter elements are modular, the UP elements may or may not be present, and it is not necessary for all of the σ elements to be recognized. However, normally at least two good σ elements must be present for recognition by RNAP in the absence of other factors. Thus, promoters can be classified as one of the three types: – 35/– 10 (the most prevalent in *E. coli*), $^{-15}\text{TG}^{-14}/-10$ (referred to as an extended – 10 promoter), and – 35/ $^{-15}\text{TG}^{-14}$. The major groove of the DNA contains the specific determinants for the σ interactions with the double-stranded DNA. For example, a classic helix-turn-helix within σ Region 4 interacts with specific base determinants on the template strand at positions – 33 and – 31 (Campbell *et al.*, 2002 and references therein). In contrast, UP elements are recognized through contacts with the minor groove of the A/T-rich sequence (Ross *et al.*, 1993; Naryshkin *et al.*, 2000). The complex that is formed by this initial binding of RNAP with the promoter is called the closed complex (RPC), since the DNA remains double-stranded or 'closed'. RPC's are typically unstable; they are usually observed only at low temperatures (4 °C) and can be challenged by the addition of a substrate that competes with the DNA, such as the polyanion heparin. Biochemical analyses suggest that in RPC, the DNA simply lies across the face of the polymerase.

Incubation of the RNA polymerase with the promoter DNA at higher temperatures (typically above 20 °C) results in the formation of the open complex (RPO), in which the DNA is unwound, generating a bubble surrounding the start site for transcription (– 12/– 11 to ~ + 5) (Figure 2, step 4). Formation of RPO involves several intermediate steps and requires major conformational changes (isomerization) within polymerase as well as the unwinding and bending of the DNA as it enters the active site of polymerase (Murakami *et al.*, 2002a; Schickor *et al.*, 1990). These changes include the movement of σ Region 1.1 out of the downstream DNA channel so that the DNA can enter (Mekler *et al.*, 2002) and the rearrangement of a portion of β' , called the clamp, into a structure that secures the downstream DNA (Saecker *et al.*, 2011; Chakraborty *et al.*, 2012). In addition, the DNA itself must bend by approximately 90° and the template strand surrounding the transcription start site must descend into the active site.

The generation of single-stranded DNA within the transcription bubble provides additional specific sites for interaction with polymerase (Lee *et al.*, 2004; Feklistov and Darst, 2011; Zhang *et al.*, 2012; Schneider, 2001; Schroeder *et al.*, 2009). σ Region 2.3 interacts with the nontemplate single-stranded DNA from – 11 to – 7 ($^{-11}\text{ATAAT}^{-7}$) with specific recognition of base determinants at the – 11A and the – 7T.

At these positions, the nontemplate base itself is 'flipped out', stacking against the aromatic ring of a residue or held in a protein pocket. Through these interactions as well as other nonspecific interactions with the -10 element, polymerase captures the nontemplate strand so that the bubble is kept open.

Other residues within σ and β also contribute important interactions with the single-stranded DNA (Zhang *et al.*, 2012; Severinov *et al.*, 1994). A structure within σ Region 3.2, the σ 'finger,' interacts with template positions -3 and -4 to place the $+1$ start site in the correct position for the incoming ribonucleoside triphosphates (rNTPs). When a GC-rich sequence (discriminator) is present in the promoter at positions -4 to -6 , residues within σ Region 1.2 can bury a nontemplate ^{-6}G within a protein pocket (Figure 1(c)) (Haugen *et al.*, 2008; Feklistov *et al.*, 2006; Travers, 1984; Zhang *et al.*, 2012). Finally, β subunit residues can interact with Core Recognition Element (CRE) present at positions -4 to $+2$ (Zhang *et al.*, 2012).

Once RPo has formed, addition of rNTPs results in the initiating complex (RPI) (Figure 2, step 5). The rNTPs enter through the secondary channel, a small channel within RNAP that leads to the active site. The RNA remains annealed to the DNA template strand for 8–9 bp. Because the polymerase is still attached to the promoter, continued synthesis 'scrunches' the DNA into the active site as the front end of the polymerase moves forward but the back end RNAP remains attached to the promoter (Figure 2, step 6; Kapanidis *et al.*, 2006). RNA longer than 9 nucleotides in length enters the RNA exit channel. However, at the start of initiation this channel is still occupied by σ Region 3.2. Consequently, promoter clearance typically requires multiple attempts, in which short RNAs are released as abortive products, causing synthesis to restart at position $+1$ (reviewed in Hsu, 2002). Finally, the emerging RNA successfully enters the channel, pushing σ Region 3.2 and helping to release σ Region 4/H5 from the grip of the β -flap. Complete release of σ , which involves disrupting the strong interaction of σ Region 2.2 with the β' CH, often accompanies formation of the elongating complex (EC) containing DNA/RNA/core polymerase (Figure 2, step 7). However, as detailed below, under certain conditions σ can remain associated with core, interacting with sequences within the DNA.

RPo is typically a very stable complex. However, for certain promoters in enteric bacteria, including the strong ribosomal promoters that account for about 70% of transcription during fast exponential growth, RPo is unstable (reviewed in Paul *et al.*, 2004; Srivatsan and Wang, 2008). Under good growth conditions, this is not a problem. The presence of a high concentration of rNTPs results in the rapid transition of the kinetically unstable RPo to a stable, initiating RPI that proceeds to elongation. When cells are slow growing or starved, the concentration of rNTPs remains high, but there is also an increase in the intracellular concentration of the small molecule ppGpp. The presence of ppGpp together with the DksA protein, which binds within the secondary channel, destabilizes the RNAP ribosomal promoter complex even further, essentially eliminating initiation (Rutherford *et al.*, 2009). In contrast, promoters within the amino acid biosynthetic pathways are activated by DksA (Gummesson *et al.*, 2013 and references therein). In this way, starved cells shift their focus

from ribosomal synthesis to pathways for amino acid synthesis and stress adaptation. Although gram positive bacteria, such as *Bacillus subtilis*, lack DksA and generate stable RPo complexes at ribosomal promoters, they still regulate expression of ribosomal RNA using ppGpp. In this case, the presence of ppGpp limits formation of GTP, which in turn restricts initiation of rRNA chains that start with GTP.

Elongation

The elongating complex (EC) is a processive transcription machine that synthesizes RNA at a rate of approximately 70 nt/s. Structures indicate that the main DNA binding channel of EC is smaller than that observed with RNAP alone. Furthermore, the 90° bend in the downstream DNA is stabilized by specific interactions with β and β' residues. These properties contribute to stability and processivity (Vassilyev *et al.*, 2007).

The heart of the EC is the active site channel where 8–9 bases of the newly synthesized RNA (red in Figure 3) are annealed to the DNA template strand at positions -1 to -9 , and the DNA template strand is located such that the $+1$ site is next to a catalytic Mg^{++} bound by core (Vassilyev *et al.*, 2007; Wang *et al.*, 2006; reviewed in Martinez-Rucobo and Cramer, 2013). For transcription to occur smoothly, the complementary NTP must be positioned correctly for catalysis, the generated pyrophosphate (PPi) must be released, and the DNA and RNA must translocate 1 base after catalysis. Several structures within the major subunits of RNAP (β and β') are thought to drive this process in an orderly manner. The β' lid loop and β' rudder lie on either side of the β' CH (Figures 3(a) and 3(b)). The β' lid loop sits at the upstream edge of the RNA: DNA hybrid, preventing an extension of more than 9 bp in the hybrid, while the β' rudder sits toward the downstream edge of the hybrid, helping to stabilize the transcription bubble. A 'switch region', composed of β and β' residues, sits at the base of the β' clamp and functions like a hinge, opening and closing the RNAP claw (reviewed in Srivastava *et al.*, 2011). This regulates how tightly the RNAP grips the DNA. One of these switches, β switch loop 3, sits just where the 5' end of the RNA extends toward the RNA exit channel and is thought to help guide the RNA toward the channel. Finally, the β' trigger loop and the β' bridge helix, which are located at the active site itself, are intimately involved in catalysis and translocation.

Structures of the EC with different substrates and inhibitors have revealed various conformations of the β' trigger loop and the β' bridge helix, leading to the following mechanism for ordered catalysis (Figure 3(b); reviewed in Kaplan, 2010; Martinez-Rucobo and Cramer, 2013). At the beginning of the process (the post-translocated state) the trigger loop is in a disordered state. If the base of the incoming rNTP (pppN) is complementary to the template base, the refolding of the trigger loop into an alpha helical structure will secure the rNTP in the correct position for insertion. Thus, the trigger loop helps to ensure accurate synthesis of the RNA. Catalysis is thought to occur through a nucleophilic substitution $\text{S}_{\text{N}}2$ mechanism, in which the 3'OH at the end of the RNA attacks the α -phosphate of the substrate rNTP. Two Mg^{++} s promote the nucleophilic attack needed to generate the phosphodiester bond. One Mg^{++} is held by core at the 3' end of the RNA; the

Positions of the bound Mg^{++} (magenta circle), the disordered β' trigger loop, and the switch region, composed of both β and β' residues, are drawn. (b) Cartoon depicting elongation. Positions of the β' lid, β' rudder, β' trigger loop (all shown in purple), the Mg^{++} (shown as magenta circle), and the 5' end of the RNA (red) are shown. PPi, pyrophosphate; pppN, ribonucleoside triphosphate.

other is transiently bound with the rNTP. After catalysis, the DNA is left in the pre-translocated state and must be translocated in order to repeat catalysis. Because different structures have revealed both straight and bent bridge helix conformations, it has been suggested that movement of the bridge helix toward the hybrid may facilitate translocation of the DNA. In addition, it is thought that PPi release may cause the trigger loop to become disordered, which returns the machine back to a state that can incorporate the next NTP.

Pausing

Although the EC is a highly processive machine, RNAP does pause for a number of reasons, such as the incorporation of a nontemplated nucleotide, the ability of RNA to adopt a secondary structure within the RNA exit channel, the presence of a lesion within the DNA, or the influence of a particular sequence. Initially, the EC enters what is called an elemental pause (reviewed in [Martinez-Rucobo and Cramer, 2013](#)). This paused state has a number of properties that disfavor synthesis: the bridge helix at the active site is in a kinked rather than straight position, the RNA exit channel is widened, the position of the switch region favors a looser binding of the RNA/DNA hybrid, and the β' clamp is in a more open state, meaning that the DNA is not as tightly held ([Weixlbaumer et al., 2013](#)). Consequently, the 3' end of the RNA misaligns relative to the template. This is referred to as 'fraying'. Elemental pauses are important because they are on the pathway for longer pauses that can lead to termination.

In the case of fraying because of a misincorporated base, translocation of the RNAP (backtracking) by 1 bp allows cleavage of the misincorporated nucleotide by the intrinsic endonuclease activity present within RNAP and the resumption of transcription ([Figure 3\(b\)](#)). However, RNAP can also backtrack by several nucleotides, causing the nucleotides at the 3' end of the RNA to become completely out of register with the template and extruded through the secondary channel ([Figure 3\(b\)](#)). In this scenario, the EC is arrested since there is no way to continue RNA synthesis. This problem can be solved by proteins called Gre factors (GreA and GreB), which insert into the secondary channel, reach the active site, and stimulate the RNAP endonuclease so that the extruded RNA is released and transcription can resume again at the +1 site ([Orlova et al., 1995](#); reviewed in [Borukhov et al., 2005](#)).

Pausing and termination are also modulated by NusA, a protein that associates with EC ([Yang et al., 2009](#); [Yang and Lewis, 2010](#)). NusA contains domains that bind to the β -flap region of RNAP and interact with RNA emerging from the exit channel ([Figure 2](#), step 8). Through these interactions, NusA promotes pausing and termination although it can also be hijacked by other proteins that enhance processivity and anti-termination. In addition, a domain of *E. coli* NusA also interacts with the α CTDs.

Another factor that associates with the EC is NusG, which binds to the β' CH, the same interaction site used by σ Region 2.1/2.2 during transcription initiation ([Figure 2](#), step 8). In *E. coli*, this factor reduces pausing and increases the rate of RNA synthesis ([Herbert et al., 2010](#)). Structures obtained using Spt5, the archaeal orthologue of NusG, together with archaeal

polymerase or a portion of the polymerase, indicate that NusG binding extends over the active site cleft and suggest a direct interaction between NusG and the nontemplate strand in the transcription bubble ([Klein et al., 2011](#); [Martinez-Rucobo et al., 2011](#)). The additional clamping provided by NusG increases the elongation rate of RNAP and discourages pausing, thereby increasing processivity. In addition, NusG interacts with the ribosomal protein S10. This is thought to connect the transcriptional and translational machineries, coordinating the rates of transcription and translation. Interestingly, NusG also interacts with the termination protein Rho (detailed below), and in this case stimulates termination ([Burmann et al., 2010](#) and references therein).

A special category of pauses is σ -dependent (reviewed in [Perdue and Roberts, 2011](#)). These pauses occur close to the promoter before σ has been released from the initiating RNAP and involve the presence of two specific sequences. First, there is a sequence that resembles one of the σ binding elements, such as AnnnT (similar to the -10 element TATAAT) together with a discriminator-like sequence or TGGATT (similar to the -35 element TTGACA). Secondly, there is a sequence that can induce RNAP backtracking (G + C rich sequence followed by an A + T-rich sequence) just upstream of the pause. It is thought that the presence of the σ binding element creates a scrunched complex much like when RNAP is trying to clear a promoter ([Figure 2](#), step 6); that is, as RNAP synthesizes RNA, the DNA is scrunched since RNAP is held by the σ /DNA interactions. (Whether σ binds the element first or RNAP pauses first is unclear.) At this point, synthesis must stop. RNAP can backtrack, relaxing the scrunch but leaving the RNA out of register. Gre-induced RNA cleavage is then needed to rescue the complex. Even though promoter-proximal pausing is important for eukaryotic gene expression and approximately 15% of *E. coli* promoters appear to contain these pauses, the purpose of the bacterial pauses is not yet clear. However, lambdoid phages use σ -dependent pausing at specific phage promoters to increase transcription of their own DNA. In this case, a phage anti-termination protein binds to the paused, scrunched complex to generate an RNAP that clears the pause and is then insensitive to downstream termination signals within the phage genome.

Termination

Correct termination of transcription at specific sites is crucial as it serves to prevent the unwanted expression of genes that are downstream of a transcribed gene. Termination occurs through two processes: (1) intrinsic termination, in which a sequence within the message alone causes RNAP to release both the DNA and RNA, and (2) factor-dependent termination, in which additional factors together with a sequence result in termination ([Figure 2](#), step 9; reviewed in [Santangelo and Artsimovitch, 2011](#); [Peters et al., 2011](#)). The typical intrinsic sequence is a GC-rich hairpin followed by a stretch of uridines. It is thought that the U-stretch results in a pause, which allows the formation of the hairpin within the RNA exit channel because of the widening of the RNA exit channel that occurs with an elemental pause. This then 'pulls' the RNA from the RNA/DNA hybrid, leading to destabilization of the EC.

Most factor-dependent termination is dependent on Rho protein, an RNA binding, ATP-dependent translocase/helicase. A hexamer of Rho proteins binds to a typically pyrimidine-rich, unstructured part of the message, called a *rut* (Rho utilization) site, and then moves along the RNA to reach the transcription machinery. Rho associates with the transcribing RNAP through an interaction with NusG, which stimulates some Rho-dependent termination. Rho causes termination at specific sequences; however, these sites are not readily predicted, although they typically correspond to a RNAP pause site. Rho is thought to function by using its translocase to push RNAP, by using its helicase to unwind the RNA/DNA hybrid, and/or by using its RNA-binding activity to pull the RNA out of the channel.

Rho serves several global needs of the cell. It clears stalled elongation complexes from the DNA, which could obstruct DNA polymerase and lead to the generation of double strand DNA breaks within the chromosome. Rho helps remove extended regions of RNA/DNA hybridization (R-loops). Finally, Rho down-regulates the expression of horizontally acquired DNA, such as prophages. In fact, deletion of such DNA results in a strain that is much less sensitive to bicyclomycin, an antibiotic that specifically inhibits Rho (Cardinale *et al.*, 2008).

Both intrinsic and Rho-dependent terminations require a conformation or a sequence within the message. Thus, factors or processes that disrupt the formation of an intrinsic hairpin or disrupt the binding of Rho to a *rut* site can result in anti-termination. Since the presence of ribosomes on RNA can prevent hairpin formation or Rho binding, active translation is a common way for the cell to prevent termination in both bacteria and archaea, where transcription and translation occur concurrently. In some cases, this provides specific regulation. For example, at the beginning of the *trp* operon, it is possible for the message to form two different hairpins (reviewed in Yanofsky, 2004; Santangelo and Artsimovitch, 2011). One of these hairpins generates an intrinsic terminator while the other hairpin (the anti-terminator) prevents the terminator hairpin from forming. Two tandem Trp codons are present in a small open reading frame just upstream of this region. When the tryptophan concentration is low, the ribosome stalls at these codons, which leads to the formation of the anti-terminator hairpin. Thus, when tryptophan is needed, the RNAP does not terminate, the *trp* operon is expressed, and tryptophan is synthesized. Conversely, transcription of the *trp* operon is prevented when more tryptophan is not needed. This type of regulation is called attenuation.

In other cases, anti-termination by stalled ribosomes is not so specific. For example, since bacterial genes are typically arranged as operons, the inability to translate a message typically allows Rho to bind, which then results in termination, preventing the expression of downstream genes. This process is called polarity (Adhya and Gottesman, 1978). Rho termination is stimulated by its interaction with NusG. However, NusG also binds to the ribosomal protein S10, and it cannot interact with Rho and the ribosome simultaneously (Burmam *et al.*, 2010). Thus, polarity may also be enhanced by the availability of NusG to interact with Rho when the ribosome is absent.

Another example occurs through a riboswitch, a specific structure in RNA whose creation is modulated by the binding

of a small molecule. If present at the appropriate location in the RNA, the folding of the riboswitch can promote or prevent the formation of an intrinsic terminator or may affect the interaction of Rho with the RNA (Hollands *et al.*, 2012 reviewed in Henkin, 2008). In this way, expression of the gene is regulated by termination in response to the controlling ligand.

Mechanisms that Regulate Bacterial Transcription

Although the presence of optimal promoter elements leads to efficient transcription, this is not ideal if expression of a gene must be controlled. Regulation requires the ability to express genes at specific times and to turn off (repress) or turn on (activate) gene expression in response to the correct conditions. Since transcription is the first step in gene expression, the process of transcription provides multiple steps for this regulation.

Repression

The easiest way to repress transcription is simply to prevent the binding of RNAP to the DNA, thus stopping R_Pc formation. Transcription of the *lac* operon is regulated by repression (Jacob and Monod, 1961). In this operon, the main operator binding site for lac repressor overlaps the promoter. Consequently, binding of a dimer of lac repressors to the operator occludes RNAP directly and prevents expression of genes needed to import and use lactose, an alternate sugar source for the cell. However, there are also weaker operator sites, upstream and downstream of the lac promoter, which can also bind lac repressor dimers. These bound dimers then form tetramers through protein-protein interactions to generate a more tightly repressed complex, a 'repressosome' (reviewed in Bell and Lewis, 2001; Wilson *et al.*, 2007).

In the case of the *gal* operon, which is needed to utilize galactose, the creation of the repressosome is required, since the operator sites only occur upstream and downstream of the promoter and binding by the repressor does not prevent RNAP binding to one of the *gal* promoters. In this case, a dimer of gal repressor binds to each operator and with the aid of the histone-like protein HU, 'loops out' the RNAP/promoter complex, preventing R_Po formation. Interactions between the repressor and the α CTDs of RNAP are thought to stabilize the RNAP/DNA complex in the inactive state (Semsey *et al.*, 2006; Choy *et al.*, 1995).

Repression of either *gal* or *lac* is relieved by the presence of a specific inducer (allolactose, a lactose metabolite for *lac* or D-galactose for *gal*). Binding of the inducer to the repressor changes its conformation and prevents its binding to the operator sites, thus allowing transcription.

Transcription can also be repressed at the step of promoter clearance. At the ribosomal promoter *rrb P1*, RNAP generates an active initiating complex R_Pi in the presence of rNTPs. However, the histone-like protein H-NS can bind simultaneously with RNAP. When H-NS is present, RNAP generates abortive transcripts, but does not proceed to elongation (Schroder and Wagner, 2000).

Figure 4 Processes that activate transcription or change promoter specificity. (a) Bacteria. Top shows RNAP/promoter complex made with σ^{70} -containing RNAP. Interactions of α CTDs and σ^{70} with promoter elements are indicated. Underneath shows examples of activation, σ^{70} remodeling, or σ switching. The position of the activator is shown in dark green while the co-activator needed for remodeling is in gray. New σ^{70} family member is in magenta. New σ^{54} member is in orange with the AAA+ activator in black. (b) Archaea. Top shows RNAP/promoter complex made at an archaeal promoter. TFB (in yellow) and TBP (in red) make up the functional equivalent of σ with TFB interacting with the BRE element and TBP interacting with the TATA element. Underneath shows example of an activator in green that is needed to recruit either TBP or TFB or the exchange of the typical TFB or TBP by TFB and TBP-related factors.

The interaction of DksA with the secondary channel of RNAP (Figure 2, step 5) also represses transcription from ribosomal promoters as well as promoters for other components of the translational machinery. DksA binds within the secondary channel, decreasing the stability of transcription initiation complexes at these promoters through the interaction of a portion of DksA (the 'tip') with the β' trigger loop (Lennon *et al.*, 2012). For repression at physiological DksA levels, this process also needs the small molecule ppGpp, which binds to a pocket formed by the ω subunit and a portion of β' , located far from the active site (Mechold *et al.*, 2013; Zuo *et al.*, 2013). Thus, allosteric changes within polymerase must be transmitted by the binding of ppGpp, which then

affect RNAP/DNA interactions in the presence of DksA. As the concentration of ppGpp rises under limiting nutrient conditions, this process redirects transcription to favor transcription of amino acid biosynthesis and alternate σ -dependent redistribution of core polymerase activity.

Activation

As promoters are composed of modular units (UP elements, -35 element, $^{-15}\text{TG}^{-14}$, -10 element), a classic activated promoter consists of a suboptimal number of elements, elements whose sequences deviate substantially from the

consensus, or elements that are not spaced correctly. Thus, these promoters will not be used efficiently by RNAP alone. However, the presence of a factor that interacts with RNAP or the DNA can facilitate the interaction of RNAP with the promoter, resulting in transcription (Figure 4(a); reviewed in Decker and Hinton, 2013; Lee *et al.*, 2012)).

Common mechanisms of activation are called Class I and Class II (reviewed in Busby and Ebright, 1999). In Class I activation, an activator binds upstream of the promoter, commonly centered at -61.5 , and interacts with α CTD's that contact DNA on either side of the activator binding site. The activator/ α CTD interactions help to 'recruit' polymerase to the promoter, thus facilitating R_Pc formation. In Class II activation, the activator binding site is just beside (commonly centered at -41.5) or even overlapping the -35 element. At this position, the activator interacts with both an α CTD that binds to the DNA upstream or to σ Region 4, which interacts with the -35 DNA. Class II activation typically facilitates both R_Pc and R_Po formation. Interestingly, some factors, such as the global activator c-AMP Receptor Protein (CRP), can function as either a Class I or Class II activator depending on the promoter. Class I and Class II activators can also function together, either using multiple activators or one activator that has more than one binding site. Such is the case for CRP, when it binds at multiple sites upstream of -70 at the *malT* promoter, and in this case, facilitates promoter clearance, the last step in transcription initiation (Eichenberger *et al.*, 1997).

Another class of activators works by 'remodeling' the DNA. These factors, exemplified by MerR, are needed at promoters whose spacer region (between the -35 and -10 elements) is longer than ideal (reviewed in Brown *et al.*, 2003). MerR binds to the spacer of the *mer* promoter and together with RNAP, generates an inactive, closed state. Upon binding Hg(II), MerR undergoes a conformation change that distorts the DNA, positioning the -10 and -35 elements correctly and allowing open complex formation. Expression of the *mer* operon then generates the proteins needed for resistance to mercury.

In contrast to its inhibition at ribosomal promoters, the interaction of DksA with the secondary channel of RNAP activates transcription from promoters that direct transcription of genes needed to respond to nutritional stress, such as promoters that drive amino acid biosynthesis. These promoters share A+T-rich discriminator sequences (as opposed to the G+C-rich discriminators at the ribosomal promoters). It is thought that the presence of DksA helps RNAP to clear the promoter, but how DksA modulates activity in response to this sequence is not yet understood (Gummesson *et al.*, 2013).

Switching the Sequence Specificity of Polymerase

The presence of alternate σ factors allows a bacterium to 'switch out' the polymerase specificity subunit, simply exchanging recognition from one set of promoters to another (Figure 4(a); reviewed in Gruber and Gross, 2003; Osterberg *et al.*, 2011). Besides σ^{70} , *E. coli* has six additional σ factors, used for flagella biosynthesis (σ^F), iron transport (σ^{FecI}), nitrogen metabolism and other cellular processes (σ^{54}) and to respond to starvation and general environmental stress (σ^S), heat shock (σ^{H1}), and unfolded proteins in the cell envelope

(σ^E). The number of σ factors encoded by a bacterial genome generally correlates with the complexity of its lifestyle. Organisms that have a varied lifestyle tend to have more σ factors. For example, *Streptomyces coelicolor*, a soil bacterium that engages in mycelial growth and spore formation, has dozens of σ factors. Because the presence of multiple σ factors would mean that there would be competition for core, there are various mechanisms, including targeted proteolysis, regulation by small RNAs, and sequestration of a σ factor by anti-sigma factors (and their regulation by anti-anti-sigma factors!) that assure that the correct σ is present at the correct time.

Since the domains of σ interact with modular promoter elements, it is possible to create a σ with different promoter specificity by remodeling one of its DNA binding domains (Figure 4(a)). Bacteriophage T4 and some T4-like phages do this by using a phage co-activator that binds and structurally alters σ Region 4 (Lambert *et al.*, 2004; reviewed in Hinton, 2010). This restructuring prevents the interaction of σ Region 4 with the -35 DNA and the interaction of σ Region 4/H5 with the β -flap. A phage activator then interacts with a specific sequence within the -30 region of the promoter and with σ H5. Thus, a new ' σ ' Region 4/promoter element is generated. Because the phage promoters retain the typical σ Region 2/ -10 element interaction, the specificity of RNAP switches from recognition of $-35/-10$ promoters to the phage $-30/-10$ promoters.

Activation of RNAP containing σ^{54}

σ^{54} , which represents the other family of σ factors, is distinct in that it requires an activating factor to generate the active transcription complex (reviewed in Wigneshweraraj *et al.*, 2005). Unlike σ^{70} , σ^{54} can bind to its promoter DNA with or without core, interacting with elements positioned at -12 and -24 (Figure 4(a)). However, the σ^{54} /RNAP/DNA complex is a stable R_Pc, which does not by itself proceed to R_Po. Isomerization to the open complex requires an ATPase-activator of the AAA+ class (ATPases Associated with various cellular Activities). An oligomer of activator binds to a region of DNA from 80 to 150 bp upstream of the promoter (referred to as a bacterial enhancer site), and then reaches the σ^{54} /RNAP/promoter complex by looping of the intervening DNA. The conformational change needed to generate the active open complex is driven by the hydrolysis of ATP. Interestingly, while most of these activators need the enhancer binding site, there are ones that work in the absence of DNA binding, suggesting that the enhancer site simply increases the local concentration of the activator (reviewed in Beck *et al.*, 2007).

Transcription and Regulation in Archaea

As seen in Figure 1(a), archaeal core contains subunits that are homologous to β' , β , the 2 α 's, and ω . More importantly, the structural features employed for RNA catalysis (β' bridge helix, β' trigger loop, switch regions, etc.) are conserved throughout biology (reviewed in Decker and Hinton, 2013; Grohmann and Werner, 2011). In particular, the structures of eukaryotic EC's are quite similar to that observed for

the bacterial EC of *T. thermophilus*. Consequently, although the structure of an archaeal EC has not yet been solved, it seems likely the fundamental process of RNA catalysis detailed for bacteria will extend to archaea. However, transcription initiation requires a specificity factor(s), and there are no archaeal or eukaryotic σ factors. In archaea, specificity is provided by TBP (TATA-binding protein) that, like eukaryotic TBP, recognizes a TATA-box [(t/a)(t/a)TATATA] centered at approximately -27 , together with TFB (Transcription Factor B), a homolog of the basal eukaryotic transcription factor TFIIB, that recognizes a specific element (called BRE) located just upstream of the TATA-box sequence (Figure 4(b)). Because TBP and TFB do not share sequence or structural homology with σ factors, the recognition of promoter elements as well as the process of open complex formation was initially thought to be substantially different between bacteria and higher organisms. However, structures (eukaryotic RNA polymerase Pol II with TFIIB (Bushnell *et al.*, 2004) and eukaryotic TBP/TFIIB/DNA (Nikolov *et al.*, 1995; Tsai and Sigler, 2000)) demonstrate that TBP/TFIIB is functionally equivalent to a σ factor. In addition, structure (Littlefield *et al.*, 1999) and photocrosslinking and EM analyses ((Renfrow *et al.*, 2004; Bartlett *et al.*, 2004; De Carlo *et al.*, 2010) reviewed in Jun *et al.*, 2011) indicate that the arrangement of archaeal TBP/TFB within polymerase is similar to that seen in eukaryotic Pol II. In particular, the important interactions of σ with core (Region 2.1/2.2 with the β' CH, Region 3.2 with the RNA exit channel, and Region 4 with the β -flap) are recapitulated by interactions between domains of TFIIB and core polymerase. Furthermore, the protein–DNA interactions of an initiating Pol II/promoter complex resemble those found in bacterial RPo, suggesting that fundamental mechanisms are retained in all organisms (Cheung *et al.*, 2011). Finally, Spt5, the homolog of bacterial NusG in archaea and eukaryotes, is also functionally homologous to NusG, increasing processivity of the elongating polymerase by interacting with the DNA upstream of the RNA/DNA hybrid (reviewed in Blombach *et al.*, 2013).

Given these similarities, it is not surprising that transcriptional regulation in archaea shares features with that observed in bacteria (Figure 4(b)). First, archaea engage in the functional equivalent of ‘sigma switching’ except that in the archaeal version, both TBP and TFB can be exchanged. For example, *Halobacterium* NRC-1 uses six TBPs and seven TFBs in various combinations (Facciotti *et al.*, 2007). As in bacteria with alternate σ factors, alternate TBP/TFB combinations can be helpful to cope with different growth conditions or times of stress. Given that TBP only interacts with one of the promoter elements (the TATA-box), the ability to exchange alternate TBPs generates a situation that bears some resemblance to bacterial σ remodeling by T4 phage.

As detailed earlier, bacterial Class I and Class II activators bind to DNA sites, interacting with subunits of RNAP (σ Region 4 and/or α CTDs) and increasing the binding of polymerase to a nonideal promoter sequence. Similarly, the *Methanococcus jannaschii* activator Ptr2 (Ouhammouch *et al.*, 2003) and the *Pyrococcus furiosus* activator PF1088 (Ochs *et al.*, 2012) bind just upstream of the BRE to recruit TBP or TFB, respectively. Thus, these archaeal activators appear to recapitulate some of the mechanisms that have been characterized in bacterial systems.

Summary

Efficient and well-controlled transcription of genomic DNA into RNA is vital to all organisms. Using a catalytic core and a σ specificity factor, the bacterial RNA polymerase proceeds through an ordered process to ensure that the genome is transcribed accurately. Transcription is regulated by factors that interact with polymerase, DNA, and RNA. Although archaeal core shares homology with the bacterial core, the archaeal specificity factor (TFB plus TBP) is not homologous to σ . Nonetheless, the interactions of TBP and TFP with core demonstrate that they are functionally similar to σ . In addition, mechanisms that activate or switch promoter specificity resemble processes seen in bacteria.

Eukaryotic Transcriptional Regulation

Introduction

Eukaryotic transcriptional regulation is an enormous topic that has been researched extensively over the past 30 years or so. Its relevance to virtually every biological process and human disease cannot be understated. Cancer, for example, is clearly due to the dysregulation of gene expression, wherein growth promoting genes (such as the c-myc oncogene) are on for too long, making too much RNA and thus too much protein. Thus, an understanding of how genes are turned on and off is of paramount importance, both as a fundamental biological problem and as a problem in human disease.

Historically, it may be useful to begin with a brief mention of some of the major thematic ideas in eukaryotic transcriptional regulation. The first major discovery was the identification of the three eukaryotic polymerases in 1969 (Roeder and Rutter, 1969), surprising because it deviated from the at-the-time paradigmatic one bacterial RNA polymerase. The next significant step was the discovery of discrete well-defined DNA sequences called promoters that established starting points for the polymerase to begin copying the gene into RNA (Dierks *et al.*, 1983, 1981). This was closely followed by the identification and purification of DNA binding proteins that could activate transcription. Concomitantly, the general factors that established transcriptionally active polymerase were purified and cloned (Thomas and Chiang, 2006). These discoveries were followed by an understanding of how packaging DNA into chromosomes affected transcriptional regulation. These thematic ideas were further extended with the discovery of chromatin modification enzymes and epigenetics. These discoveries often overlapped with each other and the demarcation of the time line of discoveries above should only be considered very coarsely. Additionally, these advances were often extensively influenced by previous work on transcription in bacteria, where several of these major themes were initially discovered. Nevertheless, these are roughly how the field has evolved, and in this article one should get a sense of the basics of transcriptional regulation in eukaryotes.

RNA Polymerases I, II, and III

There are three RNA polymerases in eukaryotes, in contrast to one in bacteria. These three polymerases, I, II, and III, transcribe ribosomal genes (pol I), protein-coding genes (pol II; and some non-coding genes/RNAs), and the 5S RNA and tRNA genes (pol III). All three are large multi-subunit enzyme complexes which share five subunits but also contain polymerase-specific subunits (Vannini and Cramer, 2012). Each polymerase has its own catalytic domain, which in pol II consists of the two largest subunits, Rpb1 and Rpb2. These two subunits comprise the cleft and trigger loop of pol II through which one strand of the DNA template threads itself. The addition of a ribonucleotide begins with the binding of an

NTP to the active site where presumably proofreading for the correct NTP occurs, followed by a metal-based catalysis that extends the RNA one base while releasing pyrophosphate. This is followed by a translocation step to move the RNA out of the active site, and allowing the cycle to begin again (Martinez-Rucobo and Cramer, 2013).

None of the three polymerases is capable of initiating transcription on its own. Instead, each polymerase requires a unique but partially overlapping set of accessory factors. The partial overlap is due to the requirement for the TATA binding protein (TBP) for all three polymerases (Vannini and Cramer, 2012). Originally discovered as a pol II-specific protein that bound to TATA box sequences in promoters (see below), it was later found to be part of the pol I and III machinery. In addition to TBP, the general transcription factor (GTF) proteins and protein complexes are necessary for the proper recruitment of the polymerase to a promoter. Among the three polymerases, the protein complement and promoter structure of the pol II genes is by far the most complex and diverse.

Promoters and Transcription Factors

The structure of a gene in general consists of an upstream promoter region that encompasses the transcriptional start site (TSS) and perhaps 50 bp of DNA downstream of the TSS. The upstream boundary of the promoter region varies but can be several kilobases in length. The core promoter comprises the region in the immediate vicinity of the TSS and in some cases defines the position of a discrete TSS. However, many genes have multiple TSSs whose positioning is not understood. Core promoter elements (CPEs) are discrete functionally defined DNA sequences that when mutated result in reduced levels of transcription. The most well-known is the TATA box (consensus sequence TATAAA) and it is found approximately 30 bp upstream of the TSS (Dierks *et al.*, 1983; McKnight *et al.*, 1981; McKnight and Kingsbury, 1982). Some promoters have an initiator element (Inr) at the TSS (consensus sequence YYA₊₁NA/TYY) (Smale and Baltimore, 1989). The Inr element can establish a TSS without need of a TATA box, although they can be found together. Bioinformatic analysis suggests that only about 10% of genes in the human genome contain TATA boxes and possibly half of all genes can be assigned known core promoter sequences. This suggests that we do not really have an understanding of core promoter architecture and TSS selection and regulation for at least half of the genome.

For many years it was assumed that no CPEs existed downstream of the TSS, but such elements have now been described in detail and display the most heterogeneity of all CPEs. The first exact sequence was the downstream promoter element (DPE), preluded by additional evidence that such elements existed (Burke and Kadonaga, 1996; Nakatani *et al.*, 1990; Smale and Baltimore, 1989). Afterwards, the downstream core element (DCE), motif ten element (MTE),

and X Core Promoter Element 1 and 2 (XCPE1 and 2) were characterized (Lim *et al.*, 2004; Lee *et al.*, 2005; Lewis *et al.*, 2000; Anish *et al.*, 2009; Tokusumi *et al.*, 2007). The DPE and DCE are the most extensively characterized, and illustrate some of the heterogeneity in downstream elements. Spacing relative to the TSS is critical as moving either the DPE or any of the three DCE subelements relative to the TSS decreases transcription (Burke and Kadonaga, 1996; Lee *et al.*, 2005; Lewis *et al.*, 2000). Similarly, spacing between the TATA box and Inr is important (Smale and Kadonaga, 2003). In the case of the DCE these spacing disruptions likely change the position of the DNA elements away from an optimal helical surface necessary for binding of the TFIID complex necessary for core promoter recognition (Lee *et al.*, 2005; Lewis *et al.*, 2000). Additionally, the sequences of all of these downstream elements are different from each other and likely bind different proteins. For example, the DPE binds the TAF6/9 component of the TFIID complex while the DCE subelements bind the large TAF1 component of TFIID (Burke and Kadonaga, 1997; Lee *et al.*, 2005). The additional distinction between the DCE and DPE in human systems is the requirement for only TFIID for DPE function while DPE function additionally requires other cofactors such as a kinase activity (Lewis *et al.*, 2005).

The core promoter functions to establish a TSS and recruit RNA polymerase II to the gene. It does so by serving as a nucleating point, recruiting the GTFs to the promoter via the various CPEs. The GTFs are the family of factors thought to be necessary for transcription from all RNA pol II-dependent genes. There are similar sets of GTFs necessary for RNA pol I and III transcription, albeit of a somewhat reduced complexity and number. The RNA pol II GTFs are TFIIA, TFIIB, TFIID, TFIIE, TFIIF, and TFIIH (Thomas and Chiang, 2006; Buratowski *et al.*, 1989; Horikoshi *et al.*, 1988; Lu *et al.*, 1991). Biochemically, the order of recruitment has been worked out. The TFIID complex binds to the core promoter via TATA box/Inr/DPE/DCE recognition along with TFIIA and TFIIB. The large TFIID complex consists of the TBP and 12 TAFs (TATA binding protein associated factors) (Thomas and Chiang, 2006). The TAFs contain the Inr, DPE, and DCE DNA binding activities as well as functioning to interact with activators (Burke and Kadonaga, 1997; Chalkley and Verrijzer, 1999; Lee *et al.*, 2005). In some cases, an activator recruits TFIID to the promoter where it then binds to various CPEs in the promoter. TFIIA/B/D recruitment to the promoter is followed by the tandem recruitment of RNA pol II and TFIIF, which in turn recruit TFIIE and TFIIH. This complex in general is referred to as the pre-initiation complex or PIC. The subsequent addition of ribonucleotides results in the melting of the DNA by the TFIIH complex helicase ERCC2 allowing RNA pol II access to a single-stranded DNA template necessary for RNA synthesis (Thomas and Chiang, 2006). It is not clear to what extent this ordered recruitment occurs *in vivo*, to what extent it occurs on different promoters with different activators and enhancers, or whether or not a paused pol II is being established. It is also not clear to what extent this model is true in the context of the discovery of many more factors involved in initiation of transcription. Indeed, *in vivo* experiments that assessed GTF recruitment during the activation of a promoter indicated that the ordered recruitment model was not observed *in vivo* (Soutoglou and Talianidis, 2002). Secondly, GTF requirements

for genes with multiple TSSs and the factor requirements for several of the DEs are not known.

The region around the TSS is typically not sufficient for higher levels of transcription; only low basal levels of transcription are obtained. Upstream of the core promoter region are often additional discrete DNA sequences that bind transcriptional activators and repressors (see below) that are necessary for high levels of transcription. Typically, these proteins are modular in their structure, consisting of a discrete DNA binding domain (DBD) such as a zinc finger motif (Ptashne, 2004). Activation of a promoter is mediated by a second domain of the protein, the transcriptional activation domain (TAD). TADs physically interact with the GTFs and the Mediator coactivator complex, a large two megadalton complex, containing 20 proteins, which interact with a variety of transcriptional activators to stimulate transcription (Poss *et al.*, 2013). Elongation factors such as P-TEFb and coactivators such as the acetyltransferases can be recruited as well (Peterlin and Price, 2006; Nagy and Tora, 2007). Both DBDs and TADs are truly modular and can function independently of one another, often being used to make hybrid DNA binding proteins and activators and which greatly facilitated their study. Furthermore, different DBDs and TADs bind different DNA sequences and coactivator proteins, respectively (Cox and Phillips, 2007). This likely allows for considerable combinatorial regulation to occur on any one gene. But it is still not clear how or whether multiple activators can stimulate a promoter concomitantly.

Enhancers are a second type of promoter activation DNA region, but can act many kilobases away from the TSS and can be positioned up- or downstream of the target promoter (Bulger and Groudine, 2010). Enhancers are a collection of activator binding sites but their histone modification signatures are distinct from promoters (Smallwood and Ren, 2013). The exact mechanism of enhancer function is not completely understood but significant advances have come from the discovery that RNA pol II-dependent transcription can begin within an enhancer and that the resulting RNA is necessary for enhancer-promoter communication. There is increasing evidence that this communication entails the physical looping of an enhancer to the target promoter (Orom and Shiekhattar, 2011).

Lastly, one final class of DNA sequences is the boundary or insulator elements. These elements function to delineate domains between genes and 'insulate' promoters from improper activation from enhancers. These boundaries are established by the CTCF protein that interacts with a boundary element, possibly by determining discrete topological domains within a chromosome that then prevent access of enhancers outside of that domain (Ong and Corces, 2014).

Transcription Initiation and Elongation

Once the PIC (pre-initiation complex) has formed at the promoter, RNA pol II is ready to begin transcribing the gene. Biochemically, the addition of the four ribonucleotides is sufficient to begin transcription. Additionally, the TFIIH complex DNA helicases, ERCC2 and ERCC3 utilize ATP to melt the double-stranded DNA, creating a transcription

bubble. RNA pol II requires bubble formation and access to single-stranded DNA to begin RNA synthesis. Concomitantly, the serine 5 residues of the RNA pol II carboxy-terminal domain (CTD) are phosphorylated by the CDK7/cyclin H kinase activity within the TFIH complex (Sims *et al.*, 2004).

Within the past 5 years or so the importance of transcriptional elongation and its regulation has become increasingly clear. In the late 1980s it was found that a subset of genes in *Drosophila* involved in the heat shock response contained an RNA pol II that was not at the promoter but was transcriptionally engaged and paused roughly 50 bp downstream of the TSS (Rougvie and Lis, 1988). It is an engaged pol II, meaning that it has a short capped mRNA and has an open DNA bubble bound by pol II. These paused polymerases were thought to encompass a minority of genes such as heat shock promoters and growth-factor-induced genes such as c-myc. The advent of genome-wide techniques changed this view and now paused pol II is thought to exist at the lower estimate of 40% of genes in the genome and thus has become quite significant (Adelman and Lis, 2012).

The predominant model of pausing requires recognition and binding of RNA pol II by the DSIF–NELF complex, which stops the elongating polymerase. The release into productive elongation occurs with the phosphorylation of DSIF (and the RNA pol II CTD serine 2 residue) by a second CTD kinase, P-TEFb. P-TEFb is thought to be regulated by various mechanisms such as recruitment by an activating transcription factor. Additionally, there are several proteins that directly affect elongation rates of RNA pol II, such as elongins, eleven nineteen lysine-rich leukemia (ELL), and TFIIS. ELL also participates in elongation as a member of the super elongation complex (SEC) (Zhou *et al.*, 2012). Additionally, the CDK7 CTD kinase activity of TFIH is also required for pausing (Glover-Cutter *et al.*, 2009; Schwartz *et al.*, 2003). Although pausing was originally thought to be necessary for rapid induction of transcription in response to stress such as heat shock, it is not a prerequisite of rapid induction. Whether pausing has a particular regulatory function or whether it is part of the evolution of additional transcriptional initiation mechanisms in higher eukaryotes is not clear.

Pol II C-Terminal Domain

The CTD of RNA pol II consists of a heptad repeat of YSPTSPS over the first 26 repeats and then diverges somewhat from the consensus sequence, predominantly at serine 7, replaced by lysine residues. Y1, S2, T4, S5, and S7 can all be phosphorylated by multiple kinases. Serine 5 phosphorylation is a prerequisite for the recruitment of capping enzyme (required for the addition of the m7G cap to the transcribed RNA) which itself binds to the phosphoserine 5 residue (Wen and Shatkin, 1999; Fabrega *et al.*, 2003). Serine 2 and serine 7 phosphorylations also recruit factors to the transcribing pol II (Egloff *et al.*, 2010, 2012). The two proline residues are targeted by the Pin1 prolyl isomerase, which converts the proline from a *trans* to *cis* conformation (Hanes, 2014). This conformational change is necessary for the recognition of phosphoserine 2 by the FCP1 phosphatase. T4 and S5 can also be O-GlcNAcylated by the O-GlcNAc transferase (Kelly *et al.*, 1993; Ranuncolo

et al., 2012). The lysines in the C-terminal half of the CTD can be acetylated by the p300 acetyltransferase, and the one R residue can be methylated by CARM1 (Sims *et al.*, 2011; Schroder *et al.*, 2013). Additionally, FCP1, RPAP2 are phosphatases acting on phosphoserines 2 and 5 respectively (Eick and Geyer, 2013; Phatnani and Greenleaf, 2006).

The phosphorylation state of the CTD is mostly important for various posttranscriptional events (Corden, 2013). These include the recruitment of proteins involved in mRNA capping, splicing, addition of the poly A tail to the mRNA, and termination of transcription. In many cases, these events are cotranscriptional, where the mRNA is processed while the RNA pol II continues the synthesis of the RNA. Histone methyltransferases (HMTs) are likewise recruited by the phosphorylated CTD cotranscriptionally and then add various combinations of methyl groups to the histone H3 tail (see below).

Termination of Transcription

The final stage of transcription is the actual termination of RNA synthesis by RNA pol II and its release from the DNA template (Proudfoot, 2011; Richard and Manley, 2009). The process begins with the cleavage factor Pcf11 binding to the serine 2 phosphorylated CTD of pol II. RNA cleavage occurs 3' to the poly A site sequence, releasing the mature mRNA from the pol II. Then a 5'–3' exonuclease (Xrn2 in humans and Rat1 in yeast) is recruited to degrade the remaining RNA presumably until contact with pol II is made and termination of RNA synthesis occurs. This model is commonly referred to as the torpedo model. Some genes also need an RNA–DNA helicase called Senataxin in humans and Sen1 in yeast, which is also recruited to the phosphorylated CTD. Among these genes are the snoRNA genes which require a complex containing Nrd1 and Nab3, along with the Sen1 helicase. More recent work suggests that these two models should be combined to create a hybrid model that incorporates the mechanisms from each, as Nrd1 has been found to colocalize with Pcf11. The Nrd1 pathway at this time only exists in yeast and no homologs of Nrd1 and Nab3 have been found in humans. Although the RNA cleavage and exonuclease degradation of the RNA are understood, it is not clear what the mechanism of termination of transcription is.

Chromatin

In the nucleus the linear DNA strand is compacted by wrapping itself around the nucleosome. A nucleosome consists of four pairs of histone proteins, H2A, H2B, H3, and H4. DNA wraps around the nucleosome 1.8 times (including the H1 linker), equivalent to 180 bp of DNA. The presence of a nucleosome creates a problem – how does a polymerase move through nucleosomal DNA (Kulaeva *et al.*, 2013)? This physical barrier requires some mechanism by which the polymerase can transcribe a gene efficiently. Facilitates chromatin transcription (FACT) was isolated using an assay designed to detect activities that could aid RNA pol II transcription on a chromatin template *in vitro*. It is thought that FACT functions as a histone chaperone, disassembling and reassembling the

histone octamer as the polymerase transcribes the DNA (Belotserkovskaya *et al.*, 2003; Hsieh *et al.*, 2013). A second problem with chromatin is that DNA binding proteins often are unable to recognize and bind their sites in nucleosomal DNA. Various chromatin remodeling complexes can move a nucleosome in an ATP-dependent manner to expose the DNA binding site (Clapier and Cairns, 2009).

One additional complexity that chromatin has is an extensive array of posttranslational modifications on the histones (Rothbart and Strahl, 2014). The N-terminus 'tail' of each histone is approximately 30 residues in length which can be acetylated, methylated, ubiquitylated, O-GlcNAcylated, phosphorylated, and citrullinated. These modifications are thought to comprise a 'histone code' and many of these serve as binding sites to recruit additional proteins involved in a variety of functions (Gardner *et al.*, 2011). For example, Brd4 has a bromodomain that binds acetylated lysines, and several proteins have chromodomains that bind methylated residues. These modifications are removed by phosphatases, demethylases, deacetylases, etc.

Each modification is associated with particular functions or states of transcription. For example, trimethyl lysine 4 (H3K4me3) modification of the H3 tail is found concentrated at the 5' ends of actively transcribed genes while H3 K36 methylation is found within the gene itself. Repressed states are associated with H3 K9 and K27 methylation, and respectively recruit the repressive HP1 and Polycomb repressive complex (PRC) to repress transcription. Similarly, active genes are heavily acetylated while histone deacetylases are parts of repressive protein complexes. The interplay and regulation of the histone code modifications is known as epigenetics and is currently under intense study.

***In Vivo* Dynamics and Behavior**

Biochemical approaches indicated that DNA binding proteins interacted with their respective specific DNA sequences with very high affinity. Stable binding was essential for their detection and characterization. However, *in vivo* studies using a variety of techniques suggest a far different picture. Residence times of transcription factors bound to DNA sites indicate rapid on/off times measured in seconds (Voss and Hager, 2014; Hager *et al.*, 2009). This has been observed with a variety of DNA binding factors and so presents a significant departure from the biochemical view of protein–DNA interactions.

Expression analysis of promoters both *in vitro* and *in vivo* has relied on a population-based approach. A promoter is linked to a gene whose expression is easily detected. For example, luciferase expression is transfected into a population of cells and changes in luciferase levels are measured upon stimulation of the promoter or by making mutations in the promoter. Similarly, *in vitro* transcription assays measure the expression of many copies of a cloned promoter added to a nuclear extract. These population assays show a continuum of expression levels.

Single-cell analysis with fluorescent microscopy shows a far different set of expression dynamics (Darzacq *et al.*, 2009). Expression levels from individual genes are stochastic, consisting of bursts of transcription followed by periods of

inactivity. This bursting can be modeled as a probability of the promoter being in either an 'on' or 'off' state. Additionally, these behaviors indicate that the equilibrium models of transcription are not correct and instead nonequilibrium conditions exist, wherein energy requirements and the thermodynamics of the kinetic processes become important. These considerations led to the random telegraph model of transcription where the frequency of initiation and the length of on–off state are stochastic processes resembling random messages sent along a telegraph wire (Larson, 2011; Palangat and Larson, 2012).

Dynamics can be seen at other levels as well. Networks of genes contain specific motifs or 'rules' that dictate time-dependent promoter behavior (Alon, 2007b; Tyson and Novak, 2010). An example of this is a feed-forward loop that involves transcription factor A turning on the expression of transcription factor B and in turn both A and B act in concert to turn on gene C. The internal behaviors of A and B then dictate the temporal expression pattern of C. In turn, these motifs are often part of a larger gene regulatory network whose cumulative expression output is governed by the collective behavior of these individual circuits.

Supercoiling

The consequence of any polymerase moving through a gene and unwinding the DNA in front of it results in the accumulation of positive supercoiling in front and negative supercoiling behind the polymerase. The positive supercoiling creates a barrier that resists any further progress of the polymerase. Continued polymerase movement requires a topoisomerase to remove this torsional stress by nicking one strand of DNA to allow its unwinding. Supercoiling thus occurs as a consequence of transcription and has important consequences for gene expression (Baranello *et al.*, 2012; Kouzine *et al.*, 2014).

Experimental Approaches

Protein Biochemistry and Transcription *In Vitro*

Gene regulation, and indeed life in general, is the manifestation of biochemistry at many different scales. The cell itself is a biochemical machine of enormous complexity. Therefore, a major effort at understanding gene regulation by necessity must comprise a thorough understanding of the underlying protein biochemistry. Protein purifications were essential to identifying and isolating the RNA polymerases, GTFs, and elongation factors, and the order they assemble on a promoter (Maldonado *et al.*, 1996). Many coactivators, DNA binding proteins, repressors, and activators were purified based on binding to their DNA sites (Ryu and Tjian, 1999; Briggs *et al.*, 1986). Similarly, histone modification enzymes were purified using assays that detected a specific posttranslational modification (Nishioka *et al.*, 2002a,b). What makes protein biochemistry so incredibly powerful is the ability to design functional assays to detect new activities and ultimately new proteins or known proteins having previously unknown functions. These assays typically rely on nuclear extracts, which are crude mixtures of proteins extracted from the nuclei of

cells. These extracts can specifically activate promoters with only the addition of ribonucleotides and the promoter DNA. The power of the biochemistry is also in its unbiased approach to identifying the proteins involved. A functionally based biochemical assay simply asks for the reconstruction of a particular activity or effect. The number of proteins or what proteins they are is irrelevant. The assay tells the researcher what protein(s) are important. In the end, it is the functional biochemistry that allows the researcher to determine protein functions directly. Many of these and other assays are discussed in detail in [Carey et al. \(2009\)](#). *The Methods in Enzymology* series and *Current Protocols* are also excellent resources.

Genetics

Biochemical approaches are complemented by the genetics of some systems, such as *Saccharomyces cerevisiae* (yeast) and *Drosophila melanogaster* (fruit flies). The success of such genetic screen approaches using yeast is apparent in the genetic identification of many of the general factors and elongation machinery, and it became apparent that many thematic ideas in transcription as well as the proteins necessary for gene expression were conserved from yeast to humans. Even before the biochemistry was worked out, *Drosophila* genetics had identified transcription factors involved in many developmental processes. Similarly, these developmental processes were highly conserved from flies to mice and humans.

The power of a genetic approach was further increased with the discovery and application of short hairpin RNAs (shRNA) to target endogenous RNAs and thereby decrease expression of the gene the shRNA is targeting. This technique has greatly expanded the tools of the biochemist in that biochemical results now can be readily tested *in vivo* without resorting to the more laborious mouse gene ablation approaches. The development of targeted RNA ablation technologies (RNAi) such as shRNA were perhaps even more important in that they basically gave researchers a tool to easily target and ablate specific genes where no genetic approaches were feasible, such as with cell lines that are growing in incubators (there is no germ-line to target). RNA ablation assays are essential tools in gathering further evidence of protein functions determined biochemically. The caveat to all genetic approaches to keep in mind is that effects may often be indirect and pleiotropic, but when combined with the more direct evidence using biochemistry, allow the researcher to understand gene regulation from several perspectives.

Other techniques greatly expanded our early understanding of transcription. Electrophoretic mobility shift DNA binding assays, and DNase I and chemical footprinting assays gave clear pictures of the DNA bound by transcription factors. Nuclear run-on experiments were essential in determining polymerase distributions across a gene and were used to first identify paused RNA pol II on *Drosophila* heat shock genes. Many of these and other assays are discussed in detail in [Carey et al. \(2009\)](#).

Molecular Biological Techniques

A significant amount of work was achieved through the use of various reporter assays that could be conducted in tissue culture. These reporter assays consisted of a DNA plasmid

containing the promoter of interest fused to a gene whose expression could be easily detected such as chloramphenicol acetyltransferase or luciferase genes. The assays for these genetic reporters are straightforward and could be done using a variety of permutations also aided by the various mutagenesis techniques developed over the years.

Genome-Wide Analysis

The past 10 years or so have seen the emergence of powerful genome-wide approaches, facilitated by the development of high-throughput DNA sequencing technologies ([van Dijk et al., 2014](#); [Furey, 2012](#)). The invention of ChIP and ChIP-seq (chromatin immunoprecipitation-high-throughput sequencing or ChIP-seq) assays were a powerful addition to the biochemist's arsenal. These approaches have given a window into the genome-wide distribution of transcription factors and unprecedented information on RNA expression levels ([Wilhelm and Landry, 2009](#); [Core et al., 2008](#); [Kwak et al., 2013](#); [Churchman and Weissman, 2011](#)). These datasets are analyzed by very sophisticated bioinformatics and computational software in order to gain insight into regulatory behaviors genome-wide.

Computational Analysis and Systems Biology

One of the newest experimental approaches to emerge is a computational one. These studies are mathematically based, utilizing data from experiments to model and understand more completely the complex behavior regulatory systems employ ([Alon, 2007a,b](#); [Milo et al., 2002](#); [Rue and Garcia-Ojalvo, 2013](#)). The data sources can be based on the ones we have already mentioned. It is these computational approaches that have added significantly to our understanding of the stochastic *in vivo* behavior of transcription dynamics ([Munsky et al., 2012](#); [Maheshri and O'Shea, 2007](#)).

Some Outstanding Issues and Questions

The following is a short list of some of the unresolved issues and questions in transcriptional regulation. There are surely more than those listed here but the list should give the reader some idea of current and future research in transcriptional regulation.

1. What is the entire content of the pre-initiation complex at promoters? What are the more physiologically relevant factors involved in transcription initiation?
2. What is the mechanism of initiation? That is, what is the signal that the PIC receives to begin transcription? What causes initiation to stop?
3. How are some genes paused and some genes not? Why are they regulated differently?
4. What is the mechanism of tissue-specific gene expression, especially when considered *in vivo* where multiple transcriptional activators can bind to the same promoter? What is the mechanism of transcription when multiple activators are employed?
5. How do transcription factors find their correct binding sites at genes where activation (or repression) is intended?

6. What is the mechanism of enhancer-mediated transcriptional activation?
7. How does the CTD of RNA polymerase II manage the variety of posttranslational modifications throughout the transcription cycle?
8. Do larger-scale structures and domains exist in the nucleus and do they have regulatory functions?
9. What is the mechanism of transcription termination?

Glossary

Activator A protein that increases gene transcription of a gene or set of genes. Most activators are DNA-binding proteins.

ATP Adenosine triphosphate, coenzyme used as an energy carrier in the cells of all known organisms.

ATP-dependent chromatin remodeler Protein complex driving the dynamic modification of chromatin architecture to allow access of condensed genomic DNA to transcription activators. Its action is driven by ATP hydrolysis.

Coactivator A protein that increases gene expression by binding to an activator (or transcription factor), which contains a DNA-binding domain. The coactivator is unable to bind DNA by itself.

Enhancer (E) A short DNA sequence capable of binding transcription regulation factors that can activate

transcription over variable distances, and independently of its orientation on DNA and position upstream or downstream of the target promoter.

Insulator A genetic boundary element that blocks the interaction between enhancers and promoters. Insulators therefore determine the set of genes an enhancer can influence.

Promoter (P) DNA region where RNA polymerase binds and initiates transcription.

Silencer A DNA sequence capable of binding transcription regulation factors that can work over a large distance and causes repression of transcription.

Super-enhancer An unusually long (~10 kb) enhancer that often activate genes defining cell identity.

Introduction

Transcriptional enhancers (Enhancers) are short (typically averaging about 700 bp in human cells) DNA sequences that can activate transcription from target promoters (Promoters, DNA regions where RNA polymerase binds and initiates transcription) over variable distances (up to more than 1 Mb), independently of enhancer orientation on DNA and its position upstream or downstream of the target promoter (Wasylyk *et al.*, 1984). Enhancers operate both in bacteria and in eukaryotes (Bondarenko *et al.*, 2003); they are predominant regulatory elements in higher eukaryotes while distant gene regulation is much less common in bacteria. However, yeast enhancer-like elements (UASs) work only over a short distance (Guarente, 1988). Over a million of enhancers regulate cell- and tissue-specific expression of human genes (Heinz *et al.*, 2010).

Action of enhancers involves communication between activated enhancer with otherwise transcriptionally silent promoter target, both already containing specifically bound proteins (Figure 1). Enhancer-promoter communication (EPC) could occur by 'hopping' or 'scanning' mechanisms proposed for translocation of *lac* repressor on DNA (Winter *et al.*, 1981). However, one class of bacterial enhancers uses a considerably different (tracking) mechanism for EPC and interaction (see below). Regardless of the precise mechanism of EPC, once the enhancer-bound protein(s) reach the target promoter, they establish direct interaction with the promoter-bound protein(s). This interaction results in local melting of promoter DNA and transcription activation. Once RNA polymerase leaves the promoter, inactive transcription complexes have to be re-established and re-activated there.

Misregulation of enhancers can lead to numerous human diseases. Thus, 93–95% of sites of single-nucleotide

polymorphism (SNPs) associated with various human diseases are localized within the non-coding regions of the genome, including multiple enhancers (Hnisz *et al.*, 2013; Thurman *et al.*, 2012; Maurano *et al.*, 2012), suggesting that enhancer malfunction is involved in development of many human diseases caused by genetic abnormalities.

Recent studies have revealed that a relatively small subgroup of enhancers called super-enhancers plays particularly important roles in cell differentiation and disease (see Lee and Young (2013) for review). Super-enhancers were discovered as regulatory elements guiding expression of genes controlling the pluripotent cell state (Whyte *et al.*, 2013). They consist of extended (~10 kb) clusters of regulatory DNA sequences that are densely occupied by the master regulators, transcription factors and mediator (Whyte *et al.*, 2013). In differentiated cells super-enhancers are present at many genes defining cell identity. The importance of super-enhancers for human health was emphasized by recent discovery of their association with many potent oncogenes expressed in cancer cells (Loven *et al.*, 2013; Hnisz *et al.*, 2013).

There are several excellent recent reviews on various aspects of enhancer action (Kulaeva *et al.*, 2012a; Krivega and Dean, 2012; de Laat and Duboule, 2013; Calo and Wysocka, 2013; Xie and Ren, 2013; Gibcus and Dekker, 2013).

Bacterial Enhancer Action

Bacteria have one four-subunit RNA polymerase core responsible for transcription of all genes and associated with one of the two types (σ^{70} - or σ^{54} -type) of sigma factor, which recognizes the promoter DNA sequence. There are two types of bacterial transcriptional enhancers using tracking and looping mechanisms for EPC, respectively.

Figure 1 Mechanisms of enhancer action over a distance. (a) Enhancer activation involves either covalent modification of the protein(s) bound to the enhancer or *de novo* protein binding; target promoters are occupied by target proteins before activation. (b) Enhancer-promoter communication occurs by one of the following ways: (a) Looping: Enhancer-bound proteins either directly interact with the target promoter, or search the spacer DNA using a hopping or scanning mechanisms. (b) Alternatively, enhancer-promoter communication occurs by tracking of enhancer-bound protein along DNA. (3) Enhancer-bound or tracking protein(s) reach the target promoter, establishing direct interaction with the promoter-bound protein(s). This interaction results in local DNA melting and promoter activation (4), followed by transcription (5). After the initial round of transcription, inactive transcription complexes have to be re-established at the target promoters to begin the activation cycle.

Distant Promoter Activation Using Tracking Mechanism

Transcription of the late genes of bacteriophage T4 is activated by the 'mobile enhancer' – a sliding clamp of T4 DNA polymerase (gp45) that is loaded on DNA at an internal nick T4-encoded protein complex gp44/62 (Latham *et al.*, 1999; Kolesky *et al.*, 2002). Once the gp45 clamp is loaded, it slides along DNA in 5'→3' direction relative to the DNA strand containing the nick. As a result, an unobstructed DNA region between the enhancer and promoter is required for enhancer action (Tinker *et al.*, 1994). When the clamp reaches the promoter, the closed initiation complex is converted into the open, functionally active complex (Kolesky *et al.*, 2002).

Distant Promoter Activation Accompanied by DNA Looping

In bacteria, the looping mechanism is employed by transcriptional enhancers activating only σ^{54} -dependent promoters (Ray *et al.*, 1990). Bacterial enhancers are involved in regulation of different metabolic pathways, ranging from nitrogen metabolism to aromatic amino acid biosynthesis (Bush and Dixon, 2012). Bacterial σ^{54} -dependent and eukaryotic enhancers share several key properties, including high stability of the closed, inactive initiation complexes, entire dependence of transcription on the presence of an activator, distant transcriptional activation (independent on exact location and orientation of the enhancer) and tight coupling of DNA melting with ATP hydrolysis (Ghosh *et al.*, 2010).

The mechanism of bacterial enhancer action is shown in **Figure 2**. Before activation, the σ^{54} -containing RNAP recognizes the promoter and forms an unusually stable closed initiation complex there (Ninfa *et al.*, 1987). Transcription initiation fully requires activators – bacterial enhancer-binding proteins (bEBPs). In contrast, regulation of σ^{70} -dependent promoters largely depends on RNA polymerase recruitment. bEBPs are members of the AAA+ protein subfamily and function by coupling the energy of ATP hydrolysis to the conversion of the closed complex to active, open initiation complex (Schumacher *et al.*, 2004). Before activation bEBPs are bound to a short (20–40 bp) enhancer DNA sequence, typically forming inactive protein dimers (**Figure 2**). Activation of bEBPs by phosphorylation or ligand binding results in a conformational change and formation of functionally

active protein heptamer (Tucker *et al.*, 2010). Then enhancer-bound bEBPs interact with the promoter-bound initiation complex and stimulate formation of the open, transcriptionally active complex at the promoter in an ATP hydrolysis-dependent way (Wedel and Kustu, 1995). Enhancer-promoter interaction is accompanied by looping of intervening DNA (Rippe *et al.*, 1997; Bose *et al.*, 2008). During short-distance EPC DNA looping is often facilitated by DNA bending induced by IHF protein (Huo *et al.*, 2009), while long-distance (over more than 1-kb distances) enhancer action requires DNA supercoiling (Liu *et al.*, 2001). DNA supercoiling induces formation of DNA ‘branches’ and thus increases the probability of juxtaposition between linearly separated enhancer and promoter (Huang *et al.*, 2001; Polikanov *et al.*, 2007). Once the bEBP is engaged with the closed initiation

Figure 2 Mechanism of action of bacterial σ^{54} -dependent enhancer. (1) Before transcription is induced, the RNA polymerase forms a closed complex at the promoter but cannot initiate transcription. Bacterial enhancer-binding protein (bEBP) is bound to the enhancer in the form of two functionally inactive dimers and does not communicate with the promoter. (2) After induction, phosphorylated bEBP assumes the heptameric oligomerization state, and (3) interacts with the closed complex causing looping of the intervening DNA and ATP hydrolysis-dependent formation of the open, functionally active initiation complex at the promoter. After formation of the active initiation complex the DNA loop is opened. (4) As the RNA polymerase leaves the promoter, the σ^{54} subunit dissociates into solution, and the closed initiation complex has to be re-assembled again.

complex through interaction with σ^{54} subunit within the ignition complex (Bose *et al.*, 2008), ATPase activity of the activator is required to induce a change in conformation of the closed complex, facilitating formation of the productive open initiation complex (Burrows *et al.*, 2009; Sharma *et al.*, 2014). As RNAP escapes from the promoter, the enhancer-promoter looping is disrupted, the σ^{54} subunit dissociates into solution and the next round of transcription requires assembly of new initiation complex at the promoter (Bondarenko *et al.*, 2002).

Enhancer Action in Eukaryotes

Gene expression in higher eukaryotes is regulated through combined action of many distant regulatory elements (enhancers, silencers (Vokes *et al.*, 2008) and insulators (Ghirlando *et al.*, 2012)) acting on core promoters (Lenhard *et al.*, 2012). Enhancers play a dominant role in regulation of gene expression and typically carry clusters of different transcription factor (TF)-binding sites. Indeed, genome-wide studies revealed that during gene activation the majority (typically >90%) of TF-binding events occur at enhancers, typically localized hundreds kb away from the regulated promoters (Young, 2011; Chen *et al.*, 2008). Histone modification patterns at enhancers are more cell type specific than promoter-associated patterns (Visel *et al.*, 2009; Ernst *et al.*, 2011), suggesting that enhancers dictate patterns of tissue-specific gene expression. There are about a million of human enhancers (Consortium *et al.*, 2012; Thurman *et al.*, 2012), with thousands of them active in a particular cell type (Visel *et al.*, 2009; Ernst *et al.*, 2011). Most promoters associate with a single enhancer, but about 25% associate with two or more enhancers (Chepelev *et al.*, 2012). During development or after induction of gene expression, the occupancy of enhancers by corresponding transcription factors is increased, inducing a particular program of gene expression (Spitz and Furlong, 2012).

The events that typically occur during enhancer-dependent promoter activation during development are illustrated in Figure 3. In early development, a subset of promoters, to-be-transcribed later in development, can be 'pre-marked' with histone modifications H3K4me3 (histone H3 tri-methylated at lysine 4 (Lindeman *et al.*, 2011; Wu *et al.*, 2011)). Later during development, pioneer factors can bind to chromatin-covered DNA that is inaccessible to other factors and recruit chromatin remodeling complexes and histone variants that destabilize nucleosomes on the enhancer and make the enhancer available for binding by other factors (Zaret and Carroll, 2011).

Later during development both enhancers and promoters destined for activation become more extensively pre-marked (Figure 3). Thus, in human and mouse embryonic stem cells, the enhancers of genes expressed early during differentiation share many properties with active enhancers (open chromatin structure, the presence of H3K4me1, TFs and coactivators (Rada-Iglesias *et al.*, 2011; Zentner *et al.*, 2011; Creyghton *et al.*, 2010)). However, in contrast to active enhancers, these 'poised' enhancers are functionally inactive (Rada-Iglesias *et al.*, 2011), contain H3K27me3 and do not contain H3K27ac (histone H3 acetylated at lysine 27 (Rada-Iglesias *et al.*, 2011; Zentner *et al.*, 2011; Creyghton *et al.*, 2010)). Corresponding

poised core promoters are inactive and contain 'bivalent' marks (H3K4me3 and H3K27me3), histone variants H3.3 and H2A.Z, and elongating (paused) RNA polymerase II (Pol II) complexes making short aborted transcripts (Marks *et al.*, 2012; Kellner *et al.*, 2012; Jin *et al.*, 2009; Golob *et al.*, 2011).

As cell differentiation unravels, different subsets of poised enhancers in different cell types are activated by cell-specific TFs and become associated with Pol II, short enhancer RNAs (eRNAs) and H3K27ac (Rada-Iglesias *et al.*, 2011; Bonn *et al.*, 2012; Figure 3). Activation of enhancers by TFs involves recruitment of coactivators, which lack sequence-specific DNA-binding competency and function as histone modifiers (e.g., acetyltransferases p300, CBP and ATAC complex), ATP-dependent chromatin remodelers (e.g., CHD7 and BAF complexes), and mediators of interaction with transcriptional machinery at promoters (e.g., Mediator complex) (D'Alessio *et al.*, 2009; Weake and Workman, 2010; Borggreffe and Yue, 2011). Active enhancers are present in nucleosome-free regions with a high rate of histone replacement and enriched for the histone variants H2A.Z and H3.3 (Mito *et al.*, 2007; Jin *et al.*, 2009).

To be activated, a gene has to be relocated from the chromosome territory (Fraser and Bickmore, 2007) into a different nuclear compartment, and chromatin structure decondensed to the level of the 30-nm chromatin fiber (Morey *et al.*, 2008). Both 'poised' (potentially active in transcription) and active chromatin domains exist in form of the 30-nm fibers (Gilbert *et al.*, 2004; Naughton *et al.*, 2010).

Similar to the NtrC-dependent enhancers, all well-studied eukaryotic enhancers work by looping: in the active state the enhancer and target promoter are in physical proximity (see Kulaeva *et al.* (2012a), Krivega and Dean (2012), Ong and Corces (2011) for review). Enhancer-promoter interaction can occur *in cis* and *in trans*; for a given E, the majority of looping interactions occur over a distance of hundreds kb (Buecker and Wysocka, 2012) and only rarely with the nearest gene (Sanyal *et al.*, 2012). In metazoan genomes, there are extensive networks of long-range interactions (see Gibcus and Dekker (2013) for review).

The 30-nm chromatin fiber is a dynamic structure that maintains efficient, distance-independent EPC; bending of the chromatin fiber required for communication is facilitated by internucleosomal interactions involving the histone tails (Kulaeva *et al.*, 2012b). Additionally, transcription of enhancers and the spacer DNA is required for enhancer action (Zhu *et al.*, 2007; Orom *et al.*, 2010; Kim *et al.*, 2010; Wang *et al.*, 2011). Two models have been proposed to explain this requirement. According to the first model, the process of transcription itself is essential, since a terminator inserted between the enhancer and promoter prevents enhancer action (Kim *et al.*, 2007; Zhu *et al.*, 2007; Ling *et al.*, 2004). Alternatively, RNA could stabilize the enhancer-promoter chromatin loop, either during or after communication (Orom *et al.*, 2010; Kim *et al.*, 2010; Wang *et al.*, 2011; Orom and Shiekhata, 2013). Numerous additional proteins and TFs are involved in the formation of chromatin loops that bring enhancers and promoters together (Marsman and Horsfield, 2012). Various enhancer-binding transcription factors (EKLF, GATA-1, and OCA-B) and cofactors (Mediator, BRG1, NLI/Ldb1, and cohesin) have been implicated in loop formation

Figure 3 Proposed mechanisms of activation of eukaryotic enhancers in development. (1) Early during development many promoters that become active later in development are pre-marked by the histone modification. (2) Later, during cell differentiation inactive enhancers are primed with pioneering transcription factors and marked by histone variants H2A.Z and H3.3. (3) Multiple inactive promoters and enhancers are poised and specifically marked in human and mouse stem cells. (4) During enhancer activation, a set of specific transcription factors binds to the enhancer, inducing enhancer-promoter communication, chromatin looping and promoter activation (5). Histone modifications and other marks that are specific for a particular development stage are shown in orange.

on different genes (Marsman and Horsfield, 2012). It should be noted that almost every factor binding at the interacting enhancer or promoter (direct or indirect, through DNA-interacting proteins) could contribute to the looping efficiency. Possible underlying mechanisms include cooperative binding of protein factors at these elements (with multiple direct and indirect mechanisms involved (Spitz and Furlong, 2012)) and stabilization of the looping *per se*, either through DNA-protein interactions (CTCF), protein-protein interactions (Mediator) or topologically enclosing interacting chromatin fibers (cohesin) (Figure 3; Marsman and Horsfield, 2012; Felsenfeld and Dekker, 2012).

After formation of the enhancer-promoter loop, activation of the promoter can occur by one of the following two mechanisms. The first mechanism involves recruiting of general transcription factor TFIID to the promoter and its activation through interaction with TFIIA, resulting in a change of TFIID conformation leading to formation of functionally

active initiation complex (Burley and Roeder, 1996; Papai *et al.*, 2010). Alternatively, enhancers can activate Pol II paused on poised promoters and protect these from inactivation by competing chromatin assembly (Min *et al.*, 2011; Golob *et al.*, 2011; Gilchrist *et al.*, 2010; Cheng *et al.*, 2012). In this case, Gdown1 protein binds to transcribing complex immediately after transcription initiation and stabilizes poised polymerase complexes stalled after transcribing 20–40 bp (Cheng *et al.*, 2012; Jishage *et al.*, 2012; Davis *et al.*, 2014). After activation by enhancer, the Pol II elongation complexes are phosphorylated by protein kinase P-TEFb and released (Czudnochowski *et al.*, 2012).

Conclusions

In summary, recent studies have identified fundamental principles of enhancer action that are valid both for bacteria

and eukaryotes. In both cases, the enhancer and promoter to-be-activated are pre-marked by inactive, stable protein-DNA complexes. Activation is induced either by modification of enhancer-bound proteins or by binding of new protein complexes at the enhancer. Then activated enhancer searches for the target using a facilitated looping mechanism (e.g., tracking) and establishes a direct interaction through protein-protein interactions with the promoter, accompanied by looping of intervening chromatin. Promoter activation typically involves a conformational change in promoter-bound protein complexes or their covalent modification.

Since enhancers are primary drivers of gene regulation in eukaryotes, they are involved in development of numerous human diseases, ranging from cardiovascular abnormalities to cancers (see Lee and Young (2013) for review).

The Spliceosome and Pre-mRNA Splicing

TJ Carrocci and AA Hoskins, University of Wisconsin–Madison, Madison, WI, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Alternative Splicing Different ways of splicing a given pre-mRNA to produce multiple distinct mRNAs.

DExD/H box A family of RNA-dependent ATPases that contain a signature DExD or DExH amino acid motif.

Exon Regions of pre-mRNA that are ligated together by the spliceosome.

Intron The regions of a pre-mRNA removed by the spliceosome.

Lariat An RNA containing a 2', 5' phosphodiester linkage that results from 5' exon cleavage during the first chemical step of splicing.

Metazoa Multicellular organisms that are members of the Animalia (Animal) kingdom.

Pre-mRNA Precursor mRNA molecules that have not been spliced and contain introns.

snRNA Small nuclear RNAs. snRNAs assemble with proteins to form the spliceosomal snRNPs.

snRNP Small nuclear ribonucleoproteins. Assemblies of snRNAs and proteins that can form spliceosomes.

Introduction

In the mid-twentieth century, eukaryotic biologists were presented with a dilemma. It had been well-established in prokaryotes that messenger RNAs (mRNAs) were direct copies of genes found within DNA. It was widely predicted that the same would hold true for eukaryotes; however, it was clear that RNA metabolism was occurring differently in organisms with a nucleus. Eukaryotic cells were found to transcribe a huge amount of nuclear RNA (called heterogeneous nuclear RNA or hnRNA) that never appeared to be exported to the cytoplasm (Sharp 1993; Soeiro *et al.*, 1966). Furthermore, both hnRNAs and mRNAs were found to contain 5' cap structures and 3' polyadenylation tracts. If hnRNAs were the precursor molecules (pre-mRNAs) to cytosolic mRNAs, how could the larger hnRNA be shortened in the middle but keep both the 5' cap and 3' polyadenylation signals at the ends intact in the mRNA? To answer this question, the laboratories of Richard Roberts and Phillip Sharp independently carried out an elegant experiment: adenovirus RNA was hybridized to its coding DNA and directly visualized by electron microscopy (Berget *et al.*, 1977; Chow *et al.*, 1977). The RNA/DNA hybrid structures revealed loops – regions of DNA not present in the mRNA. The answer was then apparent: eukaryotic mRNAs are made by cutting and ligating together different regions of a pre-mRNA. This process is called RNA splicing, and Roberts and Sharp were awarded the Nobel Prize in Medicine in 1993 for their discovery.

In the years since the discovery of RNA splicing, much has been learned about how splicing is catalyzed and how cells integrate splicing with gene regulation. The intragenic regions removed from pre-mRNAs are called introns and the retained segments are called exons. Introns are ubiquitous in eukaryotic genomes, with most human transcripts having an average of 8 introns, and ultimately several hundred thousand introns are present in the human genome (Scherer, 2008). Introns must be removed precisely: a splicing error of just one nucleotide will disrupt the correct reading frame of the mRNA. The

splicing reaction is carried out by large cellular machine made up of both RNA and proteins, dubbed the spliceosome (Brody and Abelson, 1985). The spliceosome minimally performs two functions during splicing: it defines the boundaries of the intron and then catalyzes its removal (Figure 1).

The Chemistry of Splicing and the Architecture of the Intron

The chemistry of splicing is relatively simple, comprising only two consecutive S_N2 -type transesterification reactions (Moore and Sharp, 1993). During the first catalytic step, the phosphodiester bond between the 5' exon and the intron is cleaved by nucleophilic attack from the 2' hydroxyl of the branchpoint adenosine (Figure 1(b)). The first step of catalysis results in the formation of a 2', 5' branched RNA (known as a lariat intermediate) and a free 5' exon. Rearrangements within the active site of the spliceosome then occur that permit the free 3' hydroxyl of the 5' exon to attack the intron-3' exon junction and result in the simultaneous ligation of the exons and excision of the lariat intron.

Human introns vary greatly in size from less than a hundred nucleotides to several hundred thousand (Scherer, 2008). Despite the range of intron sizes, most exons are much shorter, ranging just a few hundred nucleotides. Because of this disparity in length, selecting the proper position of the pre-mRNA for excision represents a formidable task. This problem is further complicated by the relative lack of sequence conservation between introns. Nonetheless, the spliceosome manages to recognize introns through direct interaction with consensus sequences known as the 5' splice site, the branchsite sequence, and the 3' splice site. The 5' splice site is found at the junction between the 5' exon and the intron. Downstream of the 5' splice site is the branchsite sequence containing the adenosine that serves as the branching point in the lariat intron product. The final components of the intron necessary for splicing are the polypyrimidine tract and the 3' splice site,

Figure 1 (a) The architecture of the intron. The boundaries of the intron are known as the 5' and 3' splice sites (shown in red). In addition to the splice sites, the pre-mRNA contains a branchsite region (blue) that contains the reactive adenosine (bold) necessary for catalysis. Polypyrimidine tracts are often found between the branchsite sequence and the 3' splice site. The consensus sequences as shown with *R* being any purine, *Y* being any pyrimidine, and *N* being any base. (b) The chemical steps of splicing. During the first step, the 2' hydroxyl of the branchsite adenosine (blue), attacks the 5' splice site to liberate the 5' exon and generate a lariat intermediate. In the second step, the 3' hydroxyl of the free 5' exon attacks the 3' splice site to generate the spliced mRNA and lariat intron products.

with the latter marking the junction between the intron and 3' exon. The consensus splice site and branchsite sequences in eukaryotes such as the yeast *Saccharomyces cerevisiae* are well conserved whereas these sequences are more variable in metazoans. The human consensus sequences are shown in Figure 1(a).

Despite the existence of consensus sequences, splice site recognition is complicated by the presence of both non-consensus splice sites that must be used by the spliceosome and pseudo-splice sites that must be avoided. The spliceosome can accurately discriminate *bona fide* splice sites from false signals and does so with input from other factors in nuclear RNA processing. Amazingly, the human spliceosome is proposed to properly recognize >2500 different 5' splice site sequences (Roca and Krainer, 2009). Identification of the correct splice sites is accomplished through multiple types of noncovalent interactions occurring during spliceosome assembly and activation. The spliceosome is an incredibly

sensitive and flexible enzyme that can discriminate between subtle differences in a large number of RNA sequences.

The Spliceosome is Composed of snRNAs and Proteins

Along with the discovery of introns and splicing by Roberts and Sharp, a second major breakthrough in splicing occurred when Joan Steitz proposed that small nuclear ribonucleoproteins (snRNPs, pronounced 'snurps') were the complexes that carried out the splicing reaction (Lerner *et al.*, 1980). Spliceosomal snRNPs are large complexes containing both small nuclear, uridine-rich RNAs (the 'U' snRNAs) and proteins. Sequencing of the U1 snRNA revealed that its 5' end was complementary to many 5' splice site sequences, suggesting that the U1 snRNP played a role in the splicing reaction. It was later determined that U1 along with other snRNPs assembled on pre-mRNAs into spliceosomal complexes (Wahl *et al.*, 2009).

Table 1 Comparison of the snRNP components for *Saccharomyces cerevisiae* and *Homo sapiens* spliceosomes. Cartoon structures of the human snRNAs are shown

Complex	S. cerevisiae		H. sapiens		snRNA structure
	snRNA length	No. of proteins	snRNA length	No. of proteins	
U1 snRNP	568nt	17	164nt	10	
U2 snRNP	1175nt	19	187nt	19	
U4/U6.U5 tri-snRNP	112nt 160nt 179–214nt	34	107nt 145nt 116nt	36	
Nineteen complex (NTC)	–	8	–	7	–

The core of the spliceosome is composed of four major, highly conserved subcomplexes: the U1 and U2 snRNPs, the U4/U6.U5 tri-snRNP (composed of three individual snRNPs), and the protein-only nineteen complex (NTC) (Will and Lührmann, 2011). These subcomplexes work together with a host of additional protein factors to process the RNA transcript. Each snRNP contains one or more snRNA and a variable number of snRNP-specific proteins (Table 1). The U1, U2, U4, and U5 snRNPs all contain a heptameric Sm protein ring bound to a U-rich sequence near their 3' end, while the U6 snRNA is bound by the LSM2-8 heptamer (Matera and Wang, 2014). Each snRNP serves a distinct purpose in splicing. The U1 and U2 snRNPs are responsible for recognizing the 5' splice site and branchsite sequences, respectively, through snRNA:pre-mRNA interactions. Basepairing between the U2 snRNA and the pre-mRNA branchsite sequence is responsible for positioning the reactive branchpoint adenosine by bulging it from a U2 snRNA/pre-mRNA duplex to allow for catalysis (Smith et al., 2009).

The U4/U6.U5 tri-snRNP is preassembled prior to spliceosome formation from individual U4/U6 di-snRNPs and U5 snRNPs. U4/U6 contains extensive basepairing between the U4 and U6 snRNAs. The U6 snRNA is the mostly highly conserved of the spliceosomal snRNAs, and it plays a critical role in catalysis by the spliceosome. The U6 snRNA contains at least three distinct features that are absolutely required for catalysis: the ACAGA-box (pronounced 'ah-cah-ga'), the U6 internal stem loop (ISL), and the AGC catalytic triad (Brow, 2002). The U6 ISL and AGC triad are thought to play important roles in catalysis through the coordination of catalytic metal ions, while the ACAGA-box positions the 5' splice site for exon ligation. Proper formation and alignment of these features is aided, in part, by duplex formation between the U2 and U6 snRNAs in the spliceosome. Possibly to prevent premature or aberrant splicing, the U6 ISL is disrupted in the tri-snRNP by annealing of the U6 snRNA to the U4 snRNA, which acts as a chaperone for U6. Therefore, the U4/U6 di-snRNA must be unwound prior to catalysis (Brow, 2002; Wahl et al., 2009).

The U5 snRNA is responsible for contacting the exons of the pre-mRNA to ensure proper splice site alignment

(Newman, 1997). Furthermore, the U5 snRNP contains three important protein components: Prp8, Snu114, and Brr2. Prp8 is a highly conserved 220 kDa protein that is thought to help structure and modulate the active site of the spliceosome as evidenced by a large number of chemical crosslinks between the protein and critical RNA components (Teigelkamp et al., 1995). Prp8 has been shown to interact with the U5 and U6 snRNAs, the 5' and 3' splice sites, and the branchpoint adenosine of the pre-mRNA substrate. Prp8 contains multiple protein domains including those resembling endonucleases, reverse transcriptases, and RNase H (Galej et al., 2013). The endonuclease and reverse transcriptase domains are particularly noteworthy since these resemble proteins encoded by group II self-splicing introns that facilitate DNA homing and intron insertion. This similarity suggests that at least some protein components of the spliceosome, like the snRNAs as described below, evolved from a common ancestor shared by the group II intron machinery. In addition to scaffolding the active site, Prp8 also regulates the activity of Brr2, which is responsible for unwinding the U4/U6 snRNA duplex to allow catalytic structures within U6 to form. The last unique protein component of U5, Snu114, is homologous to the translation elongation factor EF-G and uses GTP hydrolysis to further coordinate Brr2 activity (Small et al., 2006).

The final major subcomplex of the spliceosome is the NTC (Hogg et al., 2010). The NTC was named for a core spliceosomal protein, Prp19, and contains approximately seven other proteins. The NTC is required for stabilizing interactions between the U5 and U6 snRNAs with the pre-mRNA. Additionally, the NTC protein Cwc2 is essential for splicing and contacts the U6 ISL and the duplex formed between the ACAGA-box and 5' splice site (Rasche et al., 2012). This suggests that one function of the NTC may be to bring distal regions of the spliceosome into close proximity for catalysis.

The spliceosome requires many other accessory proteins not stably associated with the U snRNPs or the NTC complex to properly excise introns. For example, two important components for spliceosome assembly are splicing factor 1 (SF1), which recognizes the pre-mRNA branchsite prior to U2

association, and the U2 auxiliary factor heterodimer (U2AF35/65, also known as U2AF1/2) that binds the polypyrimidine tract and 3' splice site AG dinucleotide (Wahl *et al.*, 2009). SF1 is ultimately replaced at the branchsite by U2. Another major class of proteins that associate with the spliceosome, are the DExH/D box proteins. These proteins contain a signature sequence motif of aspartate (D), glutamate (E), usually a hydrophobic amino acid (x), and either a second aspartate or histidine (H). DExH/D box proteins are RNA-dependent ATPases that are extensively involved in RNA metabolism often through destabilization or unwinding of RNA duplexes (Jankowsky, 2011). Finally, metazoan spliceosomes are frequently associated with splicing regulatory (SR) proteins. SR proteins usually contain arginine-serine (RS) repeat motifs and help to guide spliceosome formation at the proper locations in a pre-mRNA (Long and Cáceres, 2009).

In sum, a spliceosome contains 5 snRNAs and a core set of 75 proteins that have been conserved between yeast and humans. The number of accessory proteins that have been isolated with spliceosomes in humans numbers over 300 (Jurica and Moore, 2003). The snRNPs and spliceosomes are consequently some of the largest macromolecular machines inside the cell. Due to their size and compositional complexity, only limited high-resolution crystallographic structural information is available for the individual snRNPs or spliceosomal proteins. However, lower resolution cryo-electron microscopy structures are available for several snRNPs and spliceosomal complexes. Obtaining high-resolution structural information of spliceosomes and spliceosomal components is currently being pursued by many laboratories.

Spliceosomes are Assembled from snRNPs on Introns

The spliceosome is not a static complex, but rather a dynamic machine that assembles stepwise from preformed catalytically inactive subcomplexes for each round of splicing (Hoskins *et al.*, 2011). In the canonical stepwise assembly pathway, the U1 snRNP first recognizes the 5' splice site through base-pairing of the 5' end of the U1 snRNA to the pre-mRNA (Figure 2). Elsewhere on the intron, the branchsite, polypyrimidine tract, and 3' splice sites are recognized by SF1, U2AF65, and U2AF35, respectively. Together, this forms the first intermediate in spliceosome assembly, the E complex. E complex is then converted into A complex upon ATP-dependent exchange of SF1 for U2 at the branchsite. On long introns, U1 and U2 may first interact across exons to form an exon definition complex prior to interactions that occur across the intron to be spliced (Wahl *et al.*, 2009). Regardless, A complex formation is often followed by the recruitment of the U4/U6.U5 tri-snRNP to the pre-mRNA substrate to form the catalytically inactive B complex spliceosome that contains all five of the U snRNPs. Assembly of B complex is followed by Br2-dependent activation and the formation of B^{ACT}, wherein the NTC has joined the complex, U1 and U4 snRNPs have been lost, and the active site of the spliceosome has begun to form. Activation involves multiple rearrangements that result in U6 replacement of U1 at the 5' splice site, formation of the U6 ISL, and duplex formation between the U2 and U6 snRNAs. The action of the DExD/H box protein Prp2 helps to promote the first step of catalysis (Kim and Lin, 1993), and spliceosomes capable of carrying out the chemistry of splicing are called C complexes. The first step of catalysis occurs,

Figure 2 Stepwise assembly mechanism of the spliceosome. Spliceosome assembly begins at E complex, with U1 bound at the 5' splice site, SF1 at the branchsite sequence, and U2AF65/35 at the 3' splice site. Exchange of SF1 for U2 generates A complex, which is converted into B complex upon addition of the U4/U6.U5 tri-snRNP. Activation of the spliceosome releases the U1 and U4 snRNPs from the spliceosome and generates the catalytically ready B^{ACT} complex. It is unknown if U2AF65/35 are present in the B^{ACT} spliceosome and are thus shown in lighter colors. The first step of catalysis occurs and C complex forms. After the second step of catalysis, the mRNA is released and the ILS is disassembled for further rounds of splicing.

Figure 3 The active site of the spliceosome. (a) The catalytically active spliceosome contains a complex containing the U2, U6, and U5 snRNPs. U2 and U6 snRNAs are extensively base paired with each other and the substrate. U2 makes contact with the branchsite region and results in the formation of the bulged adenosine residue that provides the nucleophile for the first step. U6 contacts the 5' splice site with the conserved ACAGAGA sequence and helps to coordinate catalytic metal ions with the AGC triad, the U6 ISL, and a bulged uridine. The U5 snRNA contacts the 5' exon to help position the substrate for catalysis. (b) Comparison of the group II intron and spliceosomal active sites. The U6 ISL is homologous the domain V of the group II intron. Both coordinate catalytic metal ions (probably Mg^{2+}) and contain similar geometries to promote catalysis. The first step of catalysis is shown for both enzymes and some group II introns can use water nucleophiles to promote 5' exon cleavage. Figures in (a) and (b) were adapted from Konarska, M.M., Vilardell, J., Query, C.C., 2006. Repositioning of the reaction intermediate within the catalytic center of the spliceosome. *Molecular Cell* 21 (4), 543–553; and Fica, S.M., Tuttle, N., Novak, T., *et al.* 2013. RNA catalyses nuclear pre-mRNA splicing. *Nature* 503 (7475), 229–234, respectively and have been used with permission of the publishers.

followed by several rearrangements within the active site facilitated by the DEXD/H box protein Prp16 that reposition the components for the second step of splicing (Schwer and Guthrie, 1991). After the second step, the spliced mRNA is released from the intron lariat spliceosome (ILS), and the post-catalytic complex is disassembled and the components are recycled for another round of splicing (Fourmann *et al.*, 2013). The spliceosome is a single turnover enzyme, meaning that the assembly and activation must occur a new on each intron to be spliced.

The Active Site of the Spliceosome

Spliceosomes must bring together distant regions of the pre-mRNA along with spliceosomal snRNAs and proteins that enable catalysis. Alignment of the reactive groups occurs in part through scaffolding of the snRNA and pre-mRNA through the basepairing interactions between the intron and the U2

and U6 snRNAs (Figure 3(a)). These reactive groups must also be aligned with the U6 ISL, and it is thought that spliceosomal proteins such as Prp8 and the NTC play key roles in juxtaposing all of these functional groups. A number of experiments have found evidence that the U6 ISL plays a key role in coordinating essential magnesium ions for catalysis (Fica *et al.*, 2013). Despite the necessity for proper alignment, the spliceosome active site must also be flexible since it is remodeled between the first and second steps of splicing to permit juxtaposition of the 5' exon and 3' splice site for exon ligation.

One striking feature of the spliceosomal active site is its similarity to that found in group II introns. Group II introns are catalytic pieces of 'self-splicing' RNA that carry out identical chemical steps (5' splice site cleavage/lariat formation and exon ligation) to those of the spliceosome. For both spliceosomes and group II introns, the chemical steps have been shown to be reversible and metal-ion dependent (Chin and Pyle, 1995; Tseng and Cheng, 2008). Remarkably, domain V of group II introns possesses many of the same catalytic

Figure 4 Kinetic proofreading during splicing. The forward reactions (toward spliced mRNA) are favored but suboptimal substrates can enter into the pre-mRNA discard pathway. Entry to these pathways is controlled by the action of the DEAH-box ATPases Prp16 and Prp22. While entry into the discard pathway is reversible, discard becomes irreversible if the spliceosomes are subsequently disassembled by the DEAH-box ATPase Prp43.

features as the U6 snRNA (Figure 3(b)). Crystal structures of group II introns have been used to model the spliceosomal active site (Fica *et al.*, 2014) and enabled experiments that found direct evidence for the presence of two catalytic magnesium ions (Toor *et al.*, 2008; Fica *et al.*, 2013). It is likely that the spliceosome and group II intron use a ‘two-metal mechanism’ (Steitz and Steitz, 1993) for catalyzing phosphodiester bond cleavage and formation with each magnesium ion playing a role in stabilizing the nucleophile or leaving group. In addition to the similarity between Prp8 domains and group II intron encoded proteins, this conservation of active site structure and mechanism between the spliceosome and group II introns provide strong evidence for evolution of the spliceosome from a group II intron-like ancestor.

DExH Box Proteins are Essential Cofactors of the Spliceosome

DExH box proteins are ubiquitously associated with processes that involve RNA, ranging from pre-mRNA splicing to mRNA translation and degradation. These enzymes couple ATP hydrolysis to RNA binding or duplex unwinding (helicase) activity in order to facilitate structural or compositional rearrangements in different RNA–protein complexes. Eight different DExH box ATPases are required for splicing: the DEAD-box proteins UAP56, Prp5, and Prp28; the DEIH-box U4/U6 unwindase Brr2; and the DEAH-box proteins Prp2, Prp16, Prp22, and Prp43 (Chang *et al.*, 2013). Each plays a distinct role in splicing. UAP56 and Prp5 are involved in spliceosome assembly; Prp28, Brr2, and Prp2 are involved in activating the spliceosome for catalysis; Prp16 and Prp22 are responsible for remodeling the catalytic spliceosome; and Prp43 is necessary for spliceosome disassembly. Consequently, while the chemical steps of splicing do not require ATP, ATP hydrolysis by DExH box proteins is necessary for splicing.

In addition to their roles in regulating spliceosomal conformational changes, several of the ATPases also have roles in splicing fidelity. Examples of this can be found in studies of the yeast homologs of Prp16 and Prp22 (Mayas *et al.*, 2006; Koodathingal *et al.*, 2010). The ATPase activity of Prp16 is involved in transitioning the spliceosome from the first to second step of catalysis. Prior to exon cleavage, Prp16 is also involved in ‘kinetic proofreading’ of suboptimal substrates (Figure 4). Spliceosomes that have assembled on pre-mRNAs with mutations in the branchsite region proceed through the catalytic steps more slowly than RNAs that contain the consensus sequences. In these suboptimal spliceosomes, hydrolysis of ATP diverts the complex from the splicing pathway to a spliceosome discard pathway. In this way, Prp16 is able to increase the fidelity of pre-mRNA splicing by rejecting suboptimal substrates or poorly assembled spliceosomes prior to the first step. This kinetic proofreading step is also seen with Prp22, which monitors the spliceosome after exon cleavage but prior to exon ligation. The DEAH-box protein Prp43 provides a critical, irreversible step during discard by disassembling these spliceosomes.

Alternative Splicing Creates Multiple Products from a Single Gene

While many introns present in eukaryotic genes are spliced from the pre-mRNA transcript constitutively, the removal of other introns can be subject to additional layers of regulation. By altering the splice site decisions during intron removal, multi-exonic transcripts can be spliced together to produce many isoforms of the same gene (Figure 5). This process is known as alternative splicing. In mammalian cells, 95% of gene transcripts are thought to undergo alternative splicing (Nilsen and Graveley, 2010). The generation of multiple mRNA isoforms from a single pre-mRNA is a powerful method to increase the protein-encoding capacity of the genome

Figure 5 Alternative splicing of a pre-mRNA. Single pre-mRNAs can generate multiple splicing products through the use of alternative splice sites. mRNA 1 contains exon 3 (green) which is not found in mRNA 2.

without increasing the size of the genome. Alternative splicing represents an important source of proteomic diversity. The most common form of alternative splicing is exon skipping in which specific exons are expressed in only a fraction of the total transcripts. Exon skipping can commonly be found in different tissue isoforms of the same gene. The first example of alternative splicing in humans was for gene encoding the peptide hormone calcitonin (Leff and Rosenfeld, 1986). Two distinct isoforms of the calcitonin mRNA exist, one that contains only exons 1–4 and a second that contains exons 1–3, 5, and 6. The first mRNA transcript is found predominately in the brain and encodes for calcitonin and the second encodes another peptide called calcitonin-gene-related peptide, which predominates in the thyroid.

Splicing is Coupled to Other Cellular Processes

Splicing does not occur in isolation but rather is connected to other cellular processes such as transcription, RNA capping, polyadenylation, and chromatin remodeling. Work in several organisms suggests that splicing can occur during or after the synthesis of pre-mRNA. Indeed, interactions between RNA polymerase II and the spliceosomal snRNPs are thought to recruit them to the nascent transcript for processing (Bentley, 2014). These interactions may ultimately influence the alternative splicing fate of the pre-mRNA. In humans and other metazoans, nuclear splicing and cytosolic translation and RNA decay can even be linked (Nott *et al.*, 2004). This occurs through deposition of a set of proteins called the exon junction complex (EJC) by the spliceosome just upstream of ligated exons. The presence of EJCs on an mRNA can have profound consequences for the fate of that mRNA once it enters the cytosol. EJCs can influence the number of proteins that can be translated from a mRNA, target the mRNA for rapid degradation, or impact other aspects of mRNA biology (Moore and Proudfoot, 2009).

Defects in Splicing Cause Disease

More than 15% of human genetic diseases arise from single point mutations that cause defects related to pre-mRNA splicing (Faustino and Cooper, 2003). These mutations can be classified as either *cis*- or *trans*-acting. *Cis*-acting mutations affect the pre-mRNA substrate, usually at constitutive or alternative splice sites but other regions of the RNA can be

affected as well. These mutations change how the pre-mRNA is processed by the spliceosome and can result in, for example, failure to remove introns, choice of incorrect splice sites, or deletions of entire exons in the mRNA. Ultimately this may change the protein that is encoded by the mRNA; sometimes by just a few amino acids as is the case in Frasier syndrome. In this disease a mutant 5' splice site causes deletion of just three amino acids from the Wilms Tumor suppressor protein, WT1, and results in severe defects in urogenital development.

Trans-acting mutations affecting the basal splicing machinery can also cause severe human diseases such as retinitis pigmentosa (RP), cancer, or spinal muscular atrophy (SMA). RP is the leading cause of inherited blindness in the world and is characterized by progressive retinal degeneration. This eventually results in total blindness from loss of rod photoreceptor cells. Several genetic causes of RP exist, with some resulting from defects in components of the U4/U6.U5 tri-snRNP, such as Prp8 or Brr2. Some cancers, such as the blood cell cancers caused by myelodysplastic syndromes, have also been found to be specifically associated with single point mutations in components of the U2 snRNP, SF1, or U2AF35/65. Degenerative neuromuscular disorders such as SMA can arise from defects in production and assembly of the snRNPs themselves. SMA is attributed to mutations in the survival of motor neuron complex, which plays a major role in the assembly of newly produced U1, U2, U4, and U5 snRNPs. Patients with SMA exhibit a progressive loss of spinal cord motor neurons leading to total paralysis of the voluntary muscles and early death.

Conclusion

The discovery of RNA splicing represented one of the great surprises in biology during the last century. Equally surprising was the complexity of the spliceosomal machinery that carries out this reaction: a multimegadalton complex of snRNAs and proteins that briefly associate together on a transcript to remove an intron before being dismantled. In addition to this complexity and transience, splicing is absolutely essential for processing of the vast majority of human mRNAs. It is likely that the complexity of the spliceosome is precisely what allows it to function on a vast array of substrates and integrate with other cellular processes to produce correct mRNAs. In the coming years advances in structural biology, biophysical methods, and genetic engineering will lead to new insights into the structures of the spliceosome and the underlying biochemical mechanisms of RNA splicing.

Introduction

Most genes in higher eukaryotes are transcribed into a pre-mRNA that is comprised of expressed sequences, called exons, and intervening sequences, termed introns. Discovered in 1977, introns are removed from pre-messenger RNA (pre-mRNA), in a process called splicing, to generate mature mRNA (Berget *et al.*, 1977; Chow *et al.*, 1977). Most pre-mRNA transcripts can undergo different patterns of splicing, defined as alternative splicing (Pan *et al.*, 2008; Wang *et al.*, 2008). The diversity in transcripts that arises through alternate splicing, and the regulation of their production, is thought to be one of the benefits of a multi-exon gene system. At the same time, a drawback of requiring the removal of introns for appropriate protein production is apparent from the prevalence of human disease-causing mutations that disrupt splicing. By some estimates, up to 60% of pathological mutations may cause aberrant splicing (Lopez-Bigas *et al.*, 2005). Mutations that affect splicing can, for example, change splicing patterns, induce the use of aberrant splice sites or alter splicing efficiency to affect gene expression by gain or loss of function coding changes that result in pathogenesis. In recent years, screens for causative mutations in human disease have identified likely pathological mutations in novel components of the splicing machinery. Interestingly, there are phenotypic themes shared between groups of splicing factors, which provide insight into the function and dysfunction of splicing in humans.

Splicing

Splicing must occur with high fidelity in order to ensure the integrity of the resulting mRNA (Semlow and Staley, 2012). Any errors in the process can result in changes in the reading frame, which would disrupt protein coding or other functional aspects of the mRNA (Hsu and Hertel, 2009). Consensus sequences, called splice sites, are found at the junctions of introns and exons and identify where splicing should occur. The 5' splice site (5'ss) defines the 5' end of an intron and the 3' splice site (3'ss) defines the 3' end (Figure 1(a)). The most common dinucleotides at the 5' and 3' ends of an intron are GU and AG, respectively, though there are noncanonical splice sites that do not conform to this rule. Many introns have a polypyrimidine tract upstream of the 3'ss which is preceded by a branchpoint sequence (BPS). The consensus sequences for these sequence elements are relatively degenerate in mammals and occur at a high frequency within a genome. Thus, they do not, themselves, provide enough sequence information to distinguish bona fide splice sites from those that match the consensus sequence of a splice site but are not used for splicing (Stephens and Schneider, 1992; Roca *et al.*, 2013). It has been a major goal of splicing research to understand how splicing

occurs with high fidelity and specificity at authentic splice sites. Much progress has been made toward understanding a so-called 'splicing code,' which predicts how splice sites, additional RNA features and proteins work together to coordinate and regulate splicing (Barash *et al.*, 2010).

Splicing Catalysis

Splicing involves two transesterification reactions that result in cleavage at the splice sites at the ends of the introns, removal of the intron, and joining the flanking exons together (Horowitz, 2012; Horowitz and Abelson, 1993). The first step of splicing involves rearrangement of snRNPs to allow a nucleophilic attack by the 2'-hydroxyl group of an adenosine in the BPS on the guanine nucleotide at the 5'ss, which results in cleavage of the 5'ss and production of an intron lariat (Reed and Maniatis, 1988). This reaction results in the formation of a 'free' upstream exon and a lariat intron contiguous with the downstream RNA. In the next transesterification reaction, the hydroxyl group at the 3' end of the upstream exon attacks the phosphodiester bond at the 3'ss. The adjoining exons are thereby covalently bound and the intron is released in the form of a lariat, which is degraded by an exonuclease, or, less commonly, processed to yield various noncoding RNAs (Hesselberth, 2013). Single-molecule studies of the splicing reaction have begun to reveal the complexity of the RNA and protein rearrangements and structural changes in the spliceosome that are required for splicing catalysis (Abelson *et al.*, 2010; Hoskins *et al.*, 2011; Figure 1(b)).

The Spliceosome

The splicing reaction is carried out by the spliceosome, a multimegadalton ribonucleoprotein complex that is comprised of small RNAs and hundreds of auxiliary proteins (Jurica and Moore, 2003). Splicing is coordinated, in large part, by five distinct uridine-rich small nuclear ribonucleoproteins (U snRNPs). Each U snRNP is comprised of a small nuclear RNA (snRNA) and auxiliary protein factors (Will and Luhrmann, 2011). The snRNA component of a snRNP confers specificity to the splicing reaction in that it base-pairs directly with the pre-mRNA to identify splice sites and direct splicing. Base-pairing between the snRNAs is essential for positioning of the pre-mRNA for the catalytic steps of splicing. The auxiliary protein components of snRNPs stabilize these relatively weak bonds and also mediate interactions with other splicing factors within the spliceosome to facilitate intron excision and exon ligation during splicing.

Spliceosomal snRNPs coordinate splicing through a process involving the specific recognition of splice sites and repositioning of RNA:RNA and RNA:protein interactions, that ultimately allows the catalytic steps of splicing. For most

Figure 1 snRNP biogenesis, recycling and pre-mRNA splicing. (a) Sequence features of human exons and introns, relevant to pre-mRNA splicing. The 5' splice site (5'ss) and 3' splice site (3'ss) define exon–intron boundaries and are bound by snRNPs, whereas the polypyrimidine tract (PY tract) and branch point sequence (BPS) facilitate spliceosome assembly and splicing catalysis respectively. (b) snRNP biogenesis begins with transcription, which occurs near the Cajal body, and shuttling to the cytoplasm for Sm protein loading via a SMN multiprotein complex. The SMN complex is shuttled with the nascent pre-snRNP back to the Cajal body within the nuclear compartment, which serves as a site of snRNP maturation and recycling. snRNPs then enter the splicing cycle, where introns are removed from pre-mRNA by a complex rearrangement mediated primarily by snRNPs and splicing factors.

introns, U1 snRNP binds to the pre-mRNA through base-pairing between the U1 snRNA and specific nucleotides of the 5'ss consensus sequence (Mount *et al.*, 1983; Roca *et al.*, 2013). U2 snRNP associates with the intronic branch site region (Query *et al.*, 1996; Will and Luhrmann, 2011). The snRNPs bind to pre-mRNAs in an ATP-dependent fashion that is assisted by auxiliary proteins such as SF1, U2AF1 (U2AF35), U2AF2 (U2AF65), and precursor RNA processing proteins (Prps) to promote and stabilize the relatively weak

associations of snRNPs to the pre-mRNA (Matera and Wang, 2014). Additional intronic features, summarized in Figure 1(a), such as the polypyrimidine tract (PY tract), which resides between the BPS and the 3'ss, also aid in the splicing process by facilitating the binding of auxiliary splicing factors such as SR proteins, hnRNP proteins, U2AF65, PUF60, and polypyrimidine tract binding proteins (PTBs) to enable subsequent spliceosomal assembly (De Conti *et al.*, 2013; Hastings *et al.*, 2007; Hastings and Krainer, 2001b).

Following U2 snRNP binding, a tri-snRNP complex, consisting of U4/U6 and U5 snRNPs, stably associates with the pre-mRNA in an ATP-dependent manner (Mroczek and Dziembowski, 2013; Roscigno and Garcia-Blanco, 1995; Turner *et al.*, 2004). U5 and U6 snRNPs interact with the 5' splice region (Kandels-Lewis and Seraphin, 1993; Newman and Norman, 1991). The U4/U6 di-snRNPs exhibit extensive base-pairing between their snRNAs, and additional shared associations between protein auxiliary factors aid binding within U4/U6 and between U4/U6 and U5 snRNP (Konarska and Sharp, 1987). Major conformational changes occur between snRNPs, pre-mRNA, and associated proteins to make the spliceosome catalytically competent for the splicing reactions.

There are two types of spliceosomes in eukaryotic cells (Patel and Steitz, 2003). The major or U2-dependent spliceosome recognizes consensus splice site sequences that define most introns. The minor or U12-dependent spliceosome, recognizes a distinct, rare type of splice site that has a unique consensus sequence (Hall and Padgett, 1996; Tarn and Steitz, 1996; Turunen *et al.*, 2013). The 5' and 3' ends of U12-type introns can be either an AU and AC, or a GU and AG. These introns were originally termed AT-AC introns for their unique AU/AC splice site dinucleotides. Both spliceosomes work in parallel, each with their own subset of U snRNPs, except for U5 snRNP, which is a component of both spliceosomes (Will and Luhrmann, 2005). Components of the minor spliceosome – U11, U12, and U4atac/U6atac snRNPs – are functional homologs of the major spliceosomal U1, U2, and U4/U6 snRNPs in the major spliceosome, respectively (Tarn and Steitz, 1996). The minor spliceosome removes ~0.3% of all introns (Sheth *et al.*, 2006; Levine and Durbin, 2001). Splicing of U12-dependent introns is similar to splicing of U2-type introns (Hastings and Krainer, 2001a; Luo *et al.*, 1999; Will *et al.*, 1999). There are some exceptions to this rule, for example, the U11/U12 di-snRNP is preformed and binds the intron as a unit rather than independently as do U1 and U2

snRNPs in the major spliceosomal reaction (Frilander and Steitz, 1999). Additionally, consensus sequence base pairing in U12-type introns is mediated via the U11-48K protein (Turunen *et al.*, 2008).

Alternative Splicing

Most splice sites can be linked together in different combinations to create more than one type of mRNA transcript from a single gene. These alternatively spliced mRNA isoforms may have different stabilities or encode protein isoforms with distinct functions (Kelemen *et al.*, 2013). Alternative splicing is a major mechanism of protein diversity in metazoans. In mammals, more than 90% of multi-exon gene transcripts are alternatively spliced (Pan *et al.*, 2008; Wang *et al.*, 2008). The main patterns of alternative splicing events are alternative 5' and 3' splice sites, mutually exclusive exons, exon inclusion/exclusion (cassette exons), and intron retention (Figure 2). Exon inclusion/exon skipping appears to be the most abundant alternative splicing event in mammals, followed by the use of alternative splice sites (Sugnet *et al.*, 2004). Although the majority of alternative splicing falls into one of these categories, there are other, less common types of alternative splicing that have been described, including the recognition of the same sequence alternatively as either a 5' splice site or a 3' splice site (Zhang *et al.*, 2007).

Alternative splicing is regulated by many of the same proteins that are involved in constitutive splicing. However, the expression of a particular splice variant is the culmination of many inputs and can be regulated at multiple levels. As may be hypothesized from a dynamic process populated by a diverse range of players, not all splice variants are generated in the same manner (Braunschweig *et al.*, 2013). Furthermore, disease-related changes to splicing dynamics can further increase the heterogeneity of splice site determination (Zhang and Manley, 2013).

Figure 2 Alternative splicing. Dominant patterns of alternative splicing include alternative use of 5' or 3' splice sites, exon inclusion or skipping (including mutually exclusive exons) and intron retention. Exons are represented by colored cylinders and introns by black lines. Alternate splicing events are shown in blue lines, which span the region removed from the pre-mRNA.

Cis-Acting Sequences and Trans-Acting Factors

A continuing issue in splicing is the question of how exons and introns are differentially identified in constitutive splicing and how recognition of splice sites is regulated in alternative splicing. There are a multitude of sequence features, both positive and negative, that contribute to the regulation of alternative splicing, including intron and exon length, protein binding sites, and secondary structure (McManus and Graveley, 2011). Splicing pathways are the result of complex combinatorial control resulting from the influence of any and all of these features within a transcript.

One example for how exon–intron sequence and organization influence RNA splicing was first proposed by Susan Berget in 1990 as the exon definition model of splicing (Robberson *et al.*, 1990). This pioneering work demonstrated that the exon was the initiating unit of spliceosome assembly and that interactions between the 3′ss and 5′ss across an exon were critical for distinguishing the correct splice sites and avoiding exon skipping. The exon definition model was supported by evidence that increasing exon sequences to more than 300 nucleotides ablated alternative splicing in most cases (Robberson *et al.*, 1990). Later, using a genome-wide approach, Bolisetty and Beemon (2012) showed that approximately 40% of large internal exons (>1000 nts) differentially spliced. The influence of exon length on exon skipping was further demonstrated by experiments showing that artificial elongation (Black, 1991) or shortening (Dominski and Kole, 1991) of exon sequences increases or decreases skipping, respectively. Furthermore, exon inclusion, even in longer exons, is promoted when the exons are flanked by shorter introns, thereby promoting interactions between the 5′ss and 3′ss across the intron (Sterner *et al.*, 1996). Overall, this and other work over that last 20 years support models that invoke splice site pairing across introns and/or exons, depending on size and other sequence features.

Splicing regulation is not limited to structural features of the mRNA transcript, as the spliceosome is associated with 100 or more protein components, many of which contribute to regulation of splicing. A large body of work exists describing the individual role of many of these proteins in alternative splicing. Two of the more well-characterized families of pre-mRNA binding splicing factors are heterogeneous ribonucleoproteins (hnRNPs), which typically bind exon-exclusion motifs (termed repressor or silencer sequences) and generally repress splicing, and Serine-Arginine rich (SR) proteins, which are best-characterized for their recognition and binding to exon inclusion sites (or enhancer sequences) (Busch and Hertel, 2012; Dreyfuss *et al.*, 2002; Manley and Krainer, 2010; Zhou and Fu, 2013). These proteins influence splicing at early stages of spliceosomal assembly. For example, SR proteins bind exon enhancer sequences and mediate the interaction between both U1 snRNA and U2AF (Anko, 2014). These splicing enhancers may also stabilize base pairing between U2 snRNA and the BPS. However, the interaction between SR proteins and pre-mRNA can be blocked by repressor sequences bound by hnRNPs, which often decrease exon inclusion (Zhu *et al.*, 2001; Martinez-Contreras *et al.*, 2007). The inhibitory effect of hnRNP binding to mRNA can also act as a steric deterrent to the core spliceosomal machinery, preventing

binding of core splicing components. In addition to their role in the early stages of spliceosome assembly, SR proteins and hnRNPs may also influence splicing later, such as the association of U6 snRNP with the 5′ splice site (Roca *et al.*, 2013). Although much work has been done to understand the role of these proteins in splicing the complexity of their interactions with each other and with RNA is still being revealed (Huelga *et al.*, 2012).

It is becoming increasingly clear that the activity of most RNA binding proteins that function in splicing is dependent on the location of binding in relationship to splice sites and binding sites for other transacting splicing factors, potentially leading to opposing functions for the same splicing factor at different splice sites (Erkelenz *et al.*, 2013; Zhou and Fu, 2013). The development of methods to identify splicing protein binding sites on RNA *in vivo* has allowed the building of binding or splicing maps for individual splicing proteins in different cell or tissue types and under different cellular conditions (Ule *et al.*, 2003). This information, along with advances in genomic and high-throughput sequencing capabilities has been invaluable as the field challenges itself with the task of understanding the splicing code that governs how splicing and alternative splicing is regulated (Hartmann and Valcarcel, 2009; Nilsen and Graveley, 2010; Wang and Burge, 2008; Barash *et al.*, 2010).

Transcription, Chromatin Structure, and Splicing

The earliest suggested point of splicing regulation is during transcription. The number of introns that are co-transcriptionally spliced is not entirely clear and can vary between species (Bhatt *et al.*, 2012; Iannone and Valcarcel, 2013; Khodor *et al.*, 2012). However, pausing of the RNA polymerase within terminal exons appears to enforce co-transcriptional splicing of the majority of introns (Carrillo Oesterreich *et al.*, 2010). Co-transcriptional splicing can regulate alternative splicing by a number of different mechanisms. First, the rate of transcription can influence competition between alternative splice sites. Slower transcription may make weaker, upstream splice sites more competitive for splicing selection as they will have more time to recruit the spliceosome before a competing splice site is transcribed (Kornblihtt, 2007). Indeed, RNA polymerase II processivity has been shown to correlate strongly with exon inclusion, with weaker splice sites included as a result of decreased transcription rate, although exceptions to this rule highlight the complexity of the interactions between splicing and transcription (Dujardin *et al.*, 2014). Transcription can also affect splice site choice through interactions between splicing and transcription factors. For example, the C-terminal domain (CTD) of RNA polymerase II interacts with a number of splicing proteins and can regulate splicing through differential phosphorylation (Du and Warren, 1997; Hirose *et al.*, 1999; McCracken *et al.*, 1997). Chromatin structure has also been implicated in alternative splicing outcomes as denser, nucleosome-rich chromatin slows transcription speed. In particular, chromatin markers, such as histone methylation, may influence splicing factor recruitment and mRNA transcript diversity, although the extent to which this affects alternative splicing is still unclear (Darnell, 2013; Luco and Misteli, 2011; Schor *et al.*, 2013).

Signaling Pathways

The effect of signal transduction pathways on alternative splicing are not well-understood, although it is likely that such signals are involved in the initiation of many, if not all, condition-specific changes in alternative splicing (Lynch, 2007). Cellular stress, immune responses, cellular differentiation, (Biamonti and Caceres, 2009; Gabut *et al.*, 2011; Martinez and Lynch, 2013; Xie and Black, 2001), and depolarization of ion channels are a few examples of potential signaling pathways that induce specific alternative splicing changes. Although work in this area is in its infancy, posttranslational modifications (PTMs) are known to influence activity, localization, expression, and protein–protein interactions. In particular, SR proteins are especially responsive to kinase activity, and many phosphorylation sites have been identified which cycle during splicing (Zhou and Fu, 2013). HnRNP and SR proteins also undergo a variety of modifications, including phosphorylation, methylation, acetylation, and SUMOylation (Sinha *et al.*, 2010). These various points of regulation suggest the spliceosome is a malleable system, which is responsive to changes in cellular dynamics.

snRNP Biogenesis

Splicing is a demanding process and the production, maturation, and recycling of the snRNPs is likely an essential part of what keeps the reaction occurring at the efficiency required to fulfill the gene expression demands of the cell and to help regulate the changes in splicing and gene expression that occur under different physiological conditions. Because of their central importance to the efficiency of the splicing reaction, the relative efficiency of these processes in different cell-types and tissues may influence splicing and play a role in the regulation of alternative splicing. The genes encoding spliceosomal snRNAs are frequently transcribed adjacent to Cajal bodies followed by export of newly synthesized snRNAs to the cytoplasm (Matera and Wang, 2014; Figure 1(b)). In the cytoplasm the SMN complex chaperones the loading of seven Sm proteins, SmB, D1, D2, D3, E, F, and G, onto an Sm consensus sequence within U1, U2, U4, and U5 snRNAs to form the heptameric Sm ring in the major spliceosome, and their corresponding snRNAs in the minor spliceosome (Fischer *et al.*, 1997; Pellizzoni *et al.*, 2002). Subsequently, snRNAs are hypermethylated at the 5'-end and trimmed at the 3'-end (Mouaikel *et al.*, 2003). Then, immature snRNPs are re-imported into the nucleus where they are initially concentrated in Cajal bodies for the secondary maturation steps. These steps involve the addition of auxiliary protein subunits specific to each particular snRNP and posttranscriptional RNA modifications, methylation, and pseudouridylation (Fischer *et al.*, 2011; Jady *et al.*, 2003). Only U6 snRNP escapes this process, and is loaded into the assembly factor SART3, which brings together U4 and U6 snRNPs primarily in Cajal bodies, prior to the assembly into the U4/U6.U5 tri-snRNP complex (Mroczek and Dziembowski, 2013; Novotny *et al.*, 2011). Mature snRNPs are released from Cajal bodies after dissociation from the SMN complex into the nucleoplasm where they participate in splicing. Thus, the biogenesis of snRNPs requires multistep maturation at cellular locations that are distinct from sites of

function. Cajal bodies are also a site of snRNP recycling after each round of splicing (Fischer *et al.*, 2011; Schaffert *et al.*, 2004; Stanek *et al.*, 2008). It should be noted that Cajal bodies are not present in all cell types (Cioce and Lamond, 2005; Dundr, 2012), but rather these nuclear bodies are present in highly proliferative aneuploid transformed cells such as cancer cells, and absent in primary diploid cells. Exceptions are fetal cells and nondividing, terminally differentiated neurons where Cajal bodies accelerate the processing of spliceosomal components more efficiently than in cells lacking them (Nizami *et al.*, 2010). Taken together, these findings strongly indicate that Cajal bodies actively participate in RNP biogenesis in both early transcriptional and late posttranscriptional nuclear steps of snRNP formation and may play a role in cell-type specific alternative splicing.

Diseases of the Spliceosome: Dysfunction Sheds Light on Function

Aberrant pre-mRNA splicing is the cause of many human diseases (Singh and Cooper, 2012). Mutations in splicing proteins or *cis*-acting splicing regulatory elements can disrupt gene expression by altering the specificity or fidelity of splicing. Mutations in *cis*-acting sequence elements can alter splicing of a single gene transcript, whereas mutations in splicing proteins may affect splicing globally. Indeed, most disease-causing mutations in splicing proteins are autosomal dominant, with the disease arising from a mutation in only one copy of the gene. These heterozygous gene mutations may result in haploinsufficiency or in the creation of a dominant negative form of the protein. The dominant nature of splicing factor mutations is not surprising considering the central role of many of the proteins in the splicing process. Different models have been proposed to explain the disease-specific phenotypes associated with spliceosomal mutations. One model is that loss of gene function reduces splicing efficiency in general, perhaps through differential affinities for various mRNA target sites. A second possibility is that poor splicing of developmental- and tissue-specific transcript(s) makes them more susceptible to deregulation following the mutation of a key regulatory splicing factor. Both models may be correct with the two outcomes operating in concert to produce each condition.

The disease conditions that are associated with mutations of particular splicing proteins offer insight into the requirements of these proteins for normal development and biological function at the organismal level. Interestingly, groups of splicing factors with similar functions have been linked to similar phenotypes and diseases, offering insights into the functional relationship between splicing processes in the cell. For example, germ-line mutations in some splicing factors cause retinitis pigmentosa (Liu and Zack, 2013; Mordes *et al.*, 2006), whereas mutations in another group of splicing factors are associated with developmental deficits including neurological, skeletal, and craniofacial abnormalities. Furthermore, somatic mutations in a number of splicing factors have been associated with hematopoietic malignancies and solid tumors (Padgett, 2012; Scott and Rebel, 2013). The reason for the manifestation of specific pathologies associated with these groups of splicing factors is not clear, though it is clear that the

human condition provides important information about the consequences of aberrant splicing at an organismal level.

Splicing Factor Mutations and Cancer

Somatic mutations in spliceosomal components have been identified in six different types of cancer to date and approximately 85% of different myeloid neoplasms with myelodysplastic features (Papaemmanuil *et al.*, 2011; Yoshida *et al.*, 2011; Makishima *et al.*, 2012), though they may not be the only causative driver of these conditions. These mutations primarily affect either auxiliary components of U2 snRNA or splicing factors involved in early steps in the splicing process during splice site recognition. Specifically, SF3B1, a component of U2 and U12 snRNPs, has been mutated in five different cancerous tissues (Biankin *et al.*, 2012; Cancer Genome Atlas, 2012; Furney *et al.*, 2013; Quesada *et al.*, 2012; Yoshida *et al.*, 2011). Hemizygous somatic mutations in another core component of the spliceosome, PRPF8, have also been identified in myeloid neoplasms and were associated with poor prognosis (Kurtovic-Kozarik *et al.*, 2014). In addition, mutations in U2AF1 and U2AF2, a non-snRNP auxiliary factor homodimer that together are required for U2 to bind pre-mRNA introns, have been linked to myelodysplasia and leukemia, respectively (Graubert *et al.*, 2012; Quesada *et al.*, 2012; Yoshida *et al.*, 2011). Similarly, ZRSR2, which interacts with the U2AF1 and the intronic sequence of the 3'ss, has also been found mutated in myelodysplasia (Shen *et al.*, 2010; Yoshida *et al.*, 2011). Also linked to cancer and involved in early events in splice site recognition and alternative splicing, SRSF1 and SRSF2 are both members of the Serine-Arginine (SR) family of splicing factors, and have been found mutated in leukemia and myeloma, respectively (Quesada *et al.*, 2012; Yoshida *et al.*, 2011). Much work is now being done to identify key splicing events that may be disrupted by mutations in these splicing factors (Brooks *et al.*, 2014; Przychodzen *et al.*, 2013).

Splicing Mutations in Retinitis Pigmentosa and Neurodegeneration

Autosomal dominant retinitis pigmentosa (RP) is a form of blindness caused by degeneration of retinal tissue that commences with either retinal pigmented epithelial cells or photoreceptor neurons. Germ-line mutations in one of 60 different genes can cause RP. Six of these RP-associated genes are linked to structure or function of the U4/U6.U5 tri-snRNP. Three of these, PRPF3, PRPF6, and PRPF31, are all auxiliary factors of the U5 snRNP or U4/U6 di-snRNP (Chakarova *et al.*, 2002; Saini *et al.*, 2012; Utz *et al.*, 2013; Vithana *et al.*, 2001; Xia *et al.*, 2004; McKie *et al.*, 2001; Tanackovic *et al.*, 2011; Grainger and Beggs, 2005; Makarova *et al.*, 2002). Interestingly, somatic mutations in one of the RP-causative genes, PRPF8 leads to myelodysplastic syndromes, as discussed above. It is not clear whether the PRPF8 germ-line mutations that cause RP also predispose individuals to myeloid neoplasms. PRPF8 has been shown to prevent the helicase hBrr2 from unwinding U4/U6 snRNPs prematurely (Mozaffari-Jovin *et al.*, 2013). Mutations in SNRNP200, the gene that encodes hBrr2 have also been shown to cause retinitis pigmentosa

(Liu *et al.*, 2012; Zhao *et al.*, 2009). Finally, RP9 (PAP-1) has been suggested to be a splicing factor, but may act as a bridge between pre-mRNA and U4/U6.U5 tri-snRNP as it has weak associations between both the tri-snRNP and U2AF1 (Keen *et al.*, 2002; Maita *et al.*, 2004).

The vulnerability of certain cell-types to mutations in components of the splicing machinery may be due to the resulting dearth of functional spliceosomes experienced by tissue that has a high amount of mRNA transcripts and therefore a high splicing demand. For example, a human tissue survey showed that retinal tissue has a disproportionately large expression of major spliceosome snRNAs relative to other tissues (Tanackovic *et al.*, 2011). Furthermore, there tends to be a higher number of Cajal bodies in cells with higher metabolic requirement such as neurons (Pena *et al.*, 2001; Spector *et al.*, 1992), which are also affected by mutations in genes encoding splicing-associated proteins. For example, mutations in the gene encoding SMN, involved in snRNP biogenesis, cause the pediatric neurodegenerative disease spinal muscular atrophy (Li *et al.*, 2014).

Splicing Mutations in Growth and Development

Germ-line mutations in a number of splicing factors have been identified as the cause of abnormal developmental and growth phenotypes in humans. These splicing factors function in relatively diverse aspects of the splicing reaction. For example, splicing factors specifically involved in the splicing of U12-type introns have been found to be mutated in conditions leading to growth hormone deficiency. Recessive mutations in the U4atac snRNA have been shown to cause the clinically most severe form of microcephalic osteodysplastic primordial dwarfism type I (MOPD I), also known as Taybi-Linder syndrome (TALS) (Edery *et al.*, 2011; He *et al.*, 2011). This condition is characterized by growth retardation, abnormal bone growth, and short stature, severe brain abnormalities in the cerebral cortex, and a life expectancy, typically, of less than 3 years. A less severe symptomatology is seen in a family with mutations in the RNPC3 gene that encodes the U11/U12-65K protein, an auxiliary protein for U12 snRNP (Argente *et al.*, 2014). The affected family members were each diagnosed with anterior pituitary hypoplasia and isolated growth hormone deficiency, type I, which leads to mild microcephaly and postnatal growth retardation. The 65K protein binds to U12 snRNA and interacts with U11 snRNP, and the mutation disrupts these associations. In these patients, an RNPC3 mutation was observed to result in splicing defects in U12-specific genes, including those related to pituitary function, possibly explaining the growth phenotype.

In addition to the mutations in U4atac and RNPC3 U12 spliceosome-associated proteins, a number of other splicing proteins have been found in individuals with short stature and digit malformations. These include PUF60 (Dauber *et al.*, 2013), and SF3B4 (Bernier *et al.*, 2012), which are associated with U2 snRNP and 3'ss recognition, and EFTUD2 which is a U5 snRNP protein (Bernier *et al.*, 2012; Luquetti *et al.*, 2013; Need *et al.*, 2012).

This partial list of splicing components encoded by genes that, when mutated, cause specific pathologies, can offer valuable information for decoding the splicing code and

understanding splicing regulation. It should be noted, that, here, we have classified the diseases by the most-dominant pathological feature arising from the mutation. However, the diseases associated with mutations in splicing factor genes often have additional phenotypes that may be less severe. This multisystem involvement highlights the central role of splicing and splicing regulation in normal cellular function.

Summary

The spliceosome is comprised of a tightly regulated, yet highly dynamic cohort of proteins and RNA transcripts. These spliceosomal players act in an organized manner, efficiently catalyzing the generation of mature mRNA transcripts. Despite this efficiency, the splicing process can also be selective as demonstrated by the prevalence of alternative splicing. Given the importance of splicing fidelity, efficiency, and regulation for proper gene expression, it is not unexpected that perturbations in core spliceosomal units and their regulatory partners have been found to be associated with various pathological dysfunctions. Intriguingly, mutations in particular splicing factors that lead to common disease phenotypes may suggest mechanistic links between the factors, the investigation of which will serve to inform our understanding of the splicing process and expose underappreciated avenues for biomedical research and subsequent innovations in clinical intervention.

Introduction

Transgenic and gene replacement strategies function to link basic biological mechanisms to organismic biology. They enable the transfer of discoveries made *in vitro* to intact organisms to provide insight into the relevance of genes and pathways in a proper context. Cell culture systems or simple unicellular organisms often do not recapitulate gene function of multicellular organisms given the interactions between cells and tissues. The role of genes within an organism is often more complex and nuanced than can be modeled reliably *in vitro*. Due to their small size and relative ease of genetic manipulation, the mouse has become the preferred model to dissect gene function and regulation related to human biology. Although much work has been devoted to mouse models, many of these technologies can and have been adapted to other organisms with unique features. For example, pigs have been genetically modified as a first step in enabling organ transplantation (Prather *et al.*, 2013). Other biological questions related specifically to humans can only be modeled in non-human primates, which have also been successfully engineered using techniques pioneered in lower organisms (Wolfgang and Golos, 2002; Sasaki *et al.*, 2009).

Genetic engineering in animals requires reliable reproductive technologies. Introducing genetic material or manipulating genes that can be transmitted through progeny requires the culture of germ cells or stem cells in order to facilitate genome engineering. Genetic material can be introduced into fertilized zygotes. Shortly after fertilization, both maternal and paternal pronuclei (encoding the haploid genomes) are prominent and easily visualized in most species. They can be directly injected before fusion (Figure 1(a)). This occurs well before germline differentiation therefore germline transmission is usually robust. Simply implanting these manipulated embryos back into surrogate females can result in genetically engineered animals even in the F0 generation. The other critical advance in reproductive technologies is the culture of embryonic stem cells.

These cells, derived from the inner cell mass of preimplantation blastocysts, can give rise to most embryonic structures including the germplasm. The specialized culture of these cells enables the manipulation and selection of genetically altered cells *in vitro*.

Figure 1 Genetic manipulation of mammals. (a) Foreign DNA can be introduced by directly injecting genetic material into the pronuclei of fertilized zygotes. These can then be transplanted back into surrogate females to generate transgenic offspring. (b) DNA can be introduced into ES cells by electroporation. Selected ES cell clones (green colonies) can be injected directly into the blastocoel of blastocyst stage embryos. Transplantation of the resultant embryos to surrogate females can result in the production of chimeric offsprings. Breeding of chimeric animals can yield ES cell-derived offsprings if the ES cells contributed to the germplasm.

The addition of these cells back to recipient blastocytes generates chimeras. Breeding of the chimeras can result in an ES cell-derived offspring given the incorporation of the ES cells into the germline (Figure 1(b)). These reproductive technologies have enabled the facile manipulation of genomes to determine gene function and regulation. The landscape of genetic manipulation is vast and seems to be inhibited only by the imagination of the investigator. There are seemingly endless variations to these basic themes that are easily adapted to answer specific questions. Here, an overview of the most widely used and informative techniques will be discussed mainly in the context of mouse models.

Transgenesis

Foreign DNA can be integrated into the germline to facilitate the understanding of gene regulation or function. Transgenics can be made in a rather straightforward manner by injecting DNA (usually linearized plasmid DNA) into the pronuclei of mammalian zygotes. This facilitates random integration of DNA into the genome that can be stably propagated to successive generations through the germline. Gene regulation can be deciphered in this manner by linking putative regulatory sequences of a gene of interest to a reporter gene (Zimmerman *et al.*, 1994). There are many convenient reporter genes available to monitor gene regulation in a cell-specific manner in both fixed tissue and live mice. β -Galactosidase activity, encoded by LacZ, can be used to understand tissue-specific gene expression even in harshly fixed tissue. This strategy has been used widely to understand gene regulation in transgenics due to its stability and convenience. To understand gene regulation in living cells, fluorescent proteins such as green fluorescent protein (GFP) can be used to directly visualize fluorescent cells *ex vivo* or via intravital imaging *in vivo* (Weigert *et al.*, 2013; Ellenbroek and van Rheen, 2014). This can enable rather sophisticated analysis of gene expression in living cells. Most fluorescent proteins have a long half-life, however, short-lived or photoconvertible fluorescent proteins can be used to obtain a more precise timing of expression. Additionally, noninvasive means of monitoring gene expression in living mice can be accommodated by using luciferase-based reporter genes (Wilsbacher *et al.*, 2002). Luciferase bioluminescence can be imaged directly in live mice noninvasively over a long time-scale. Even secreted forms of luciferase (e.g., Gaussia princeps luciferase) can be used to understand gene regulation by minimally invasive techniques such as repeated blood sampling (Wurdinger *et al.*, 2008).

The transcriptional regulation of genes sometimes goes well beyond what can be accommodated within a simple plasmid. For genes that have critical regulatory elements encoded far away from their coding sequences, one can turn to bacterial artificial chromosomes (BACs) to produce transgenics. BACs often recapitulate gene expression more precisely as they contain hundreds of kilobases of genomic DNA surrounding the coding sequence. BACs, although more laborious to work with than simple plasmids, can be recombineered by standard techniques in bacteria to encode reporter genes within the coding sequence (Gong *et al.*, 2010). This approach has been successfully adapted to large-scale gene mapping projects to

mark gene expression patterns *in vivo* (Gong *et al.*, 2003). One drawback of BACs besides their unwieldy size is that they often contain other genes linked to the gene of interest, which has the potential to unintentionally modify phenotypes.

Going beyond marking cells of interest or unraveling the regulation of genes *in vivo*, understanding gene function using transgenics is also of great interest. Over-expression of genes or expressing constitutively active or dominant negative genes aids in unraveling gene functions *in vivo* (Moitra *et al.*, 1998). Additionally, early work defining cell- and tissue-specific regulatory elements have made tissue-specific expression of transgenes routine. Therefore, one can define the role of genes in a tissue-specific manner by expressing transgenes *in vivo*. Inclusion of a synthetic intron or an insulator sequence is an important consideration that can greatly enhance the expression of transgenes.

Some of the earliest studies facilitated transgenesis using simple retroviruses like Moloney murine leukemia virus (MMLV) to integrate new genetic material into mouse embryos and subsequently transmitted to progeny through the germline (Jaenisch, 1976). Unfortunately, simple retroviruses are transcriptionally suppressed under most circumstances, limiting their usefulness in promoting transgenesis. Circumventing this transcriptional suppression is the use of lentiviruses that can support the expression of genes in mammals (Pfeifer *et al.*, 2002; Lois *et al.*, 2002). Injecting DNA into pronuclei often generates concatemeric random insertion that can effect transgene expression and function depending on the local genetic landscape. One advantage of lentivirus-mediated transgenesis is that single transgene copies are inserted randomly throughout the genome therefore permitting single transgene integration. These random integration methods can sometimes disrupt endogenous gene function and can be heavily influenced by their genomic environment. These issues can be greatly mitigated by introducing transgenes into predetermined transcriptionally permissive integration sites such as the R26 or H11 loci. Several mouse lines have been produced to facilitate entry of exogenously provided DNA into these loci (Tasic *et al.*, 2011).

Temporal Regulation of Transgenes

It is often not possible to regulate the temporal expression of transgenes using tissue-specific promoters. Some promoters can be regulated by exogenous factors (e.g., interferon or metal ions), however, these are often hindered by significant off-target effects. Steroid-responsive promoters that are engineered to respond to unique steroids such as the synthetic progesterone receptor antagonist mifepristone or the insect steroid ecdysone can be used to facilitate temporal expression (Wang *et al.*, 1997). These methods are robust and specific temporal regulators but are somewhat cost prohibitive for *in vivo* experimentation. A more popular and versatile means of regulating mammalian transgene expression is the use of the bacterial tetracycline-responsive operon. Tetracycline or its analogue doxycycline binds to and regulates the tetracycline repressor (TetR). The TetR has been modified to allow both positive (Tet-On) and negative (Tet-Off) transgene expression in response to doxycycline. Tet-Off works by activating

transgene expression in the absence of doxycycline, whereas Tet-On activates transgene expression in the presence of doxycycline. The Tet system has been widely used to regulate gene expression in transgenic animals. Doxycycline crosses the blood–brain barrier and can be given simply by adding it to drinking water (Chen *et al.*, 1998). This allows versatile regulation of transgenes in many settings.

In addition to regulating the transcriptional control of transgenes, transgenes can be regulated via posttranslational means as well. Introduction of fusion proteins that can be regulated by small molecules can control the localization of transgenes. Addition of a steroid receptor to a transcription factor or to Cre recombinase can sequester the protein within the cytoplasm. Providing the ligand can enable the translocation to the target and access to the substrate (Feil *et al.*, 1996; Kohn *et al.*, 1998; Metzger *et al.*, 1995). Additionally, fusion of proteins with small molecule-regulated destabilizing domains or inducible dimerization domains can mediate temporal regulation of transgene function (Rodriguez *et al.*, 2014; Rodriguez and Wolfgang, 2012; Banaszynski *et al.*, 2006; Rakhit *et al.*, 2014). Some transgenes can even be activated by light. These techniques can provide not only tissue-specific expression but also temporal-specific expression or function.

Loss of Function

A basic reductionist approach to determining gene function *in vivo* is the generation of knockout animals. Loss-of-function strategies can greatly inform the role of a gene in the context of an organism by deciphering the gene's requirements for a phenotype of interest. Many investigations into lower organisms make use of forward genetic screens using randomly induced mutagenesis to assign gene function to an assayed phenotype. Although this strategy has been used in mammals, the cost and scale of genetic screens is largely prohibitive. Understanding mammalian gene function is usually done in one or a few genes at a time via gene-targeting strategies of well-annotated genes. Although laborious, the results of these reverse genetic strategies are usually enormously enlightening, focus on further experimentation, and form the foundation for much of modern biomedical sciences.

Gene Trap

One means of determining gene requirements is the use of gene traps to both mark and inactivate genes (Skarnes *et al.*, 2004). Gene traps utilize simple retroviruses containing a splice acceptor linked to a reporter gene (e.g., LacZ or GFP) and a selectable cassette with a polyadenylation sequence to short circuit gene expression. Self-inactivating MMLV vectors can be used to limit the transcriptional inhibition inherent in these vectors, therefore mitigating some of their limitations. MMLV retroviruses pseudo-randomly integrate into the genome by preferentially integrating into large permissive introns making them ideal for gene trapping in ES cells. In this way, clonal heterozygous ES cell traps can be isolated and selected for the production of chimeras and subsequent breeding for mice with homozygous gene disruptions. Additionally, if a

reporter gene is placed into the vector downstream of the splice acceptor then one can determine the endogenous gene expression pattern of the trapped gene by assaying for the reporter gene in the heterozygous or homozygous offspring (Zambrowicz *et al.*, 1997). One of the major limitations to this method is that alternative splicing, which occurs widely throughout the genome, can often mask true null phenotypes. More sophisticated trapping methods can be used to understand, for example, the regulation of transcriptional targets of critical signaling pathways and subsequently the requirements for these targets *in vivo* (Chen *et al.*, 2004). Gene trapping methods have been used extensively to understand gene requirements *in vivo* but have been somewhat outpaced by more stringent gene-replacement technologies.

Homologous Recombination

To generate a more reliable means of reverse engineering mammalian animal models, investigators have employed homologous recombination in ES cells to ensure correctly targeted alleles. This is done routinely in several inbred strains of mice. In species where germline competent ES cells have not been routinely used, homologous recombination can be performed in somatic cells followed by nuclear transfer (i.e., cloning) (Dai *et al.*, 2002). Homologous recombination in ES cells is by far the most popular method owing to the stringency and user-defined nature of reverse genetics and is now routinely used throughout biomedical sciences. Homologous recombination is mediated by the electroporation of a selectable cassette (usually antibiotic resistance) that is flanked by 3–10 kb of homologous arms of genomic DNA. The classic method for disrupting a gene is to target a critical exon by omitting the exon from the targeting vector. Therefore, the removal of the exon and replacement with an antibiotic resistant minigene disrupts the gene throughout the organism. Knockin alleles can also be produced in this manner by replacing an exon with exon-containing amino acid substitutions to determine the role of specific mutations on gene function.

Simple gene replacement has been largely supplanted by the generation of more versatile conditional alleles via Cre/Lox technology. Cre recombinase recognizes and recombines a 34 bp lox site (Araki *et al.*, 2002). Two such sites placed in tandem in the same orientation can be recombined generating a minicircle and thus the genomic sequence can be removed between the sites. This allows for tissue-specific or temporal deletion of genes within organisms expressing Cre in a tissue-specific or inducible manner. Many mice have been generated and are widely available that express a tissue-specific or temporally regulated Cre recombinase for most applications. Lox sites are generally placed surrounding a critical exon and the antibiotic resistance cassette is placed within an intron. The resistance cassette is often flanked by Frt sites that can be recombined within germplasm by Flpe recombinase. The goal is to preserve wild-type function of the gene by having minimal foreign-derived sequences that are embedded in putatively inert introns. Cre recombinase can be used to remove sequences if placed in the same orientation or they can be used to invert sequences if placed in the opposite orientation. Cre recombinase is used routinely for the deletion of small

sequences but has also been used to rearrange large sections of chromosomes (Zheng *et al.*, 1999). Additionally, transgenes can be controlled by Cre-mediated recombination by placing genes after a lox-stop-lox cassette (Reamy and Wolfgang, 2011; Rodriguez and Wolfgang, 2012). In this way the large array of Cre recombinase-expressing mice can be brought to bear to regulate transgene expression in a cell-type or temporal manner *in vivo*. Homologous recombination and gene replacement are used in almost every field of biomedical science to inform gene function and regulation in a stringent manner *in vivo*.

Precision Genome Editing

The loss or gain of gene function in transgenic animals has been invaluable for understanding the role of these genes in human development, physiology, or pathophysiology. Removing gene function is not always the most valuable means of studying a gene particularly in the context of understanding the role of human mutations in disease progression. Human mutations are rarely true null alleles, but are usually point mutations that disrupt the proteins' function. Understanding how specific mutations or amino acid modifications affect protein function also has enormous value. The classic means of studying specific mutations is to introduce the mutation by homologous recombination to generate a knockin allele essentially as described above. This is often informative but is laborious to develop these animal models. Genome editing via DNA targeted endonucleases has been extremely efficient at targeting specific DNA sequences via a streamlined production that enables multiple gene editing simultaneously (Hauschild *et al.*, 2011). Originally, zinc finger nucleases (ZFNs) directed toward specific DNA sequences were used to target an endonuclease to generate DNA breaks at specified sequences (Miller *et al.*, 2007). Generating double-stranded DNA breaks induces an error-prone non-homologous end joining that often results in site-specific frame-shift mutations. Additionally, the induction of a DNA break greatly increases the efficiency of homologous recombination at the site of the break. Therefore, providing homologous DNA encoding a site-specific mutation along with the nuclease enables efficient gene editing that can be accomplished within the zygote. Injection of the target-specific nucleases into pronuclear embryos or ES cells can rapidly induce frame-shift mutations or enable gene editing.

Generating target-specific ZFNs requires a great deal of selection and optimization that has limited their broader use. In a similar fashion, transcription activator-like effector nucleases (TALENs) have been used to target endonucleases to specific sequences. The DNA-binding properties of the Tal effectors from *Xanthomonas* are straightforward such that the generation of site-specific binding TALENs can be done in a rather programmable manner. TALENs have proven to be more user friendly, target specific, and effective and have been used to genetically engineer a wide range of species (Sung *et al.*, 2013). Another leap in this technology has been the development of the clustered regularly interspaced short palindromic repeat (CRISPR) system for site-specific DNA engineering of mammalian cells (Mali *et al.*, 2013). CRISPR utilizes a Cas9 endonuclease that is targeted to DNA by a short guide RNA (gRNA). Because the

DNA-binding specificity is encoded by the gRNA, this system is incredibly user friendly and is easily adapted to the species of interest with little optimization (Li *et al.*, 2013; Niu *et al.*, 2014; Wang *et al.*, 2013; Yang *et al.*, 2013). Additionally, since the endonuclease is targeted by the gRNA, multiple sites can be engineered simultaneously by simply providing multiple gRNA sequences. Remarkably, this has been used to target and mutate multiple alleles to homozygosity in a single generation. These facile and exciting genome-editing technologies will likely enable even greater dissection of gene function *in vivo*.

Conclusion

Generating transgenic and knockout animals has proven to be enormously effective at deciphering the molecular mechanisms by which genes operate within complex organismal settings. Genome engineering that was once only feasible in simple organisms such as fungi or invertebrates is not routinely done in mammalian species, even toward the use in nonhuman primate models. Transgenic and gene-replacement technologies that are now available to investigators are vast and can be either straightforward such as the removal of a single gene of interest or can be incredibly nuanced to answer ever more specific questions. Enhancing, removing, or manipulating genes in mammals is central to many research programs aimed at understanding human biomedical sciences and these technologies are continuously growing and improving to provide ever more accessible and informative *in vivo* models.

Viral Nucleic Acids

IP O'Carroll and A Rein, National Cancer Institute at Frederick, Frederick, MD, USA

Published by Elsevier Inc.

Glossary

Cis-acting signal A sequence or structure in a nucleic acid molecule that confers some functional property on the molecule, but this property is confined to the molecule containing the signal and cannot be transferred to other molecules.

Encapsidation Incorporation of nucleic acid into an assembling virus particle.

Icosahedron A solid with 20 faces. Many 'spherical' viruses are regular icosahedra, with 20 equilateral triangular faces and 12 axes of 5-fold symmetry.

Trans-acting factor A factor, typically a protein, produced within a cell and capable of conferring a functional property on other molecules or complexes. For example, a viral genome might contain a *cis*-acting signal enabling it to be packaged into assembling virus particles, while a protein supplied by an expression vector might be incorporated into the virus particles and affect their host range.

Virion Virus particle.

Introduction

Viruses are the most abundant organisms on earth (Breitbart and Rohwer, 2005; Suttle, 2005). An Avogadro's number of infections occurs every second in the world's oceans (Suttle, 2013). Their role in the ecology of the oceans is so significant that they affect the global carbon cycle and contribute to climate change (Danovaro *et al.*, 2011). If placed end to end, marine viruses would span a distance 70 times the diameter of our galaxy.

At the most basic level, a virus particle is a package containing nucleic acid. The packaging material is protein encoded by the nucleic acid. The particle can enter cells and, taking advantage of the cellular biosynthetic machinery, direct the production of progeny virus particles identical to the infecting parent.

This scheme in turn places two requirements on the nucleic acid: it must be replicated in the virus-producing cell, to provide the genetic material encased in the progeny virus particles; and it must encode the proteins needed for the production of the progeny particles, including at a minimum the structural proteins from which the particles will be assembled. The particles are always composed of multiple copies of a limited number of proteins; this fact has fundamental implications regarding particle structure (Crick and Watson, 1956).

The diversity of nucleic acids found in viruses is startling. Viruses may contain: linear double-stranded (ds) DNAs; circular ds DNAs; linear or circular single-stranded (ss) DNAs; coding ('+' strand) RNAs; RNAs ('-' strand) whose complements encode viral proteins; and dsRNAs. In some RNA-containing viruses ('ambisense'), part of the RNA is + strand and part is - strand; in some, individual virus particles contain multiple RNA molecules, which together constitute the viral genome and all of which are required for successful replication of the virus; in others, the RNAs required for replication are distributed among different particles. Some virus particles contain RNA, but this RNA is copied into DNA when the virus infects a new host cell. The size and complexity of viruses also varies over an enormous range: the nucleic acids may contain

as few as 2000 bases or more than 2×10^6 bases, corresponding to coding capacities ranging from two proteins to over 2000 proteins.

Obviously, all viruses extant today have survived by virtue of successful strategies for replicating themselves (Koonin and Dolja, 2013). Therefore, each virus has a way of both replicating and expressing its nucleic acid; these strategies exploit the tools available within the susceptible host cell. In turn, viruses are incomparable sources of information about cellular processes; indeed, much of our most fundamental knowledge about biology, including the fact that DNA is the repository of genetic information in cells and that DNA is copied into mRNA for its expression, has been obtained using viruses (Brenner *et al.*, 1961; Hershey and Chase, 1952; Judson, 1996).

Table 1 presents a partial listing of the nucleic acids in different virus families. One of the most fundamental distinctions between viruses is whether they contain DNA or RNA. As cellular genetic information is carried in DNA, many DNA viruses rely on cellular machinery for both replication of their genomes and production of mRNA transcripts for gene expression. In contrast, cells do not normally make copies of RNA molecules; thus, RNA viruses must encode the proteins needed for RNA replication, including the RNA-dependent RNA polymerase.

As the cellular machinery for replication and transcription of DNA is in the cell nucleus, those viruses using this machinery must perform these tasks in the nucleus. This includes all but very large DNA viruses: the latter, including the poxviruses and the newly discovered *Megaviridae*, encode their own synthetic machinery and replicate in the cytoplasm. Another striking difference between DNA and RNA viruses is in the range of their genome sizes: while the largest RNA virus genomes, those of the coronaviruses, are approximately 32 kb, DNA viral genomes can be nearly 100 times larger, as Pandoravirus DNA is approximately 2.5×10^6 bp.

Despite the amazing variety in the nucleic acids present in virus particles, these nucleic acids must all be replicated by standard Watson-Crick mechanisms: every coding strand must be copied into a noncoding strand of opposite polarity, and

Table 1 Diversity of viral genomes^a

	<i>ds/ss</i>	<i>Polarity</i>	<i>Genome structure</i>	<i>Segments</i>	<i>Factors bound to genome</i>	<i>Genome length</i>	<i>Example of virus family/genus^b</i>

^aViral genomes are grouped based on type of nucleic acid (DNA/RNA), whether it is double-stranded (ds) or single-stranded (ss), polarity (+/–), genome structure (Linear/Circular), number of segments, and the presence or absence of factors bound to the genome. For each group, the range of genome size is given.

^bFor simplicity, only one virus family is shown as an example for each group. It is important to remember that this table indicates the size-range of genomes for all members of a given group, and not merely for the example shown in the last column.

vice versa. The other absolute requirement is that somehow an RNA (or RNAs) of the coding strand must be produced for translation into the virus-coded proteins. The various pathways of information transfer to mRNA are summarized in [Figure 1](#), and were well summarized over 40 years ago ([Baltimore, 1971](#)). It is important to realize that viral nucleic acids possess, in addition to protein-coding sequences, *cis*-acting signals that often perform essential functions in virus replication. Examples are sequences recognized by viral proteins for packaging the genomic nucleic acid into progeny virus particles and sequences required for initiation of complementary nucleic acid strands. In general, when viral genomes are engineered for use as vectors, the sequences encoding viral proteins can be replaced and the needed proteins provided in *trans*, but the *cis*-acting signals must be preserved to permit replication of the vector.

Group I: dsDNA Viruses

We have known for many years that dsDNA viruses vary over a wide range in size and complexity, extending from the

polyomaviruses (~5 kbp) to the poxviruses (~130–365 kbp). Very recently, even far larger dsDNA viruses have also been discovered; these ‘giant viruses’ that have been isolated to date only infect amoebae. Although the genomes of these newly isolated viruses have been sequenced, little is known about their biology or the structure of their DNA as yet ([Hendrix, 2009](#); [Yutin and Koonin, 2013](#)).

As far as is known, all DNA synthesis in living systems is primer-dependent: in other words, DNA chains are not synthesized *de novo*, but only by addition of deoxynucleotides to a preexisting macromolecule (the primer). In cellular DNA synthesis, the primers for one of the two strands are short RNA molecules. dsDNA viruses use a variety of primers in DNA synthesis. The DNA of SV40, a member of the Polyomavirus family, is replicated by the same basic mechanisms as cellular DNA ([Figure 2\(a\)](#); [Stenlund, 2003](#)). In contrast, in both adenoviruses and hepadnaviruses, the primer is a viral protein: the new DNA chain is initiated by addition of a deoxynucleotide to an –OH group on the side-chain of a specific amino acid in a virus-coded protein ([Figure 2\(b\)](#); [Van der Vliet, 1995](#)). In other dsDNA viruses, special structures in the DNA are involved in its replication. For example, poxvirus genomic DNAs

Figure 1 Information pathways in viral mRNA synthesis. The nature of the nucleic acid in the virus particle is indicated in groups I–VII (green boxes). Dark blue and light blue wavy arrows represent positive and negative sense DNA strands, respectively, whereas red and orange wavy arrows represent positive and negative sense RNA strands, respectively. The direction of the wavy arrows indicates polarity (5' to 3'). Straight, black arrows represent a copying step. The two parallel gray lines represent equivalency.

Figure 2 Replication strategies of DNA viruses. (a) Bidirectional replication in dsDNA viruses, (b) DNA strand displacement in dsDNA viruses, (c) rolling hairpin replication in ssDNA viruses. Dark blue lines represent DNA template in the 5' to 3' direction and light blue lines represent the complementary DNA template strand. Dark blue arrows indicate synthesis of the new DNA strand in the 5' to 3' direction. Red lines represent RNA primers. Green-filled shape represents a protein that serves as a primer.

are covalently closed: while replication of their DNAs is still not fully understood, these structures are critical for this process (Figure 2(b)). In many dsDNA viruses, the protein shell is preformed, and the DNA is then pumped into the shell, with the help of energy from ATP, by elaborate 'motor' machinery. This apparatus is best characterized in the case of dsDNA bacteriophages, but analogous mechanisms are apparently used by the herpesviruses as well. The DNA is packed at extremely high density in the fully formed virus particle.

Group II: ssDNA Viruses

The ssDNA viruses include some of the smallest and simplest viruses, with genomes only approximately 2–6 kb in length. One of these viruses is the familiar dog pathogen, canine parvovirus. These small viruses rely on the host cell (and, for some ssDNA viruses, coinfecting larger viruses) for much of their replication machinery. These 'minimalist' viruses may encode only a single structural protein and a single protein involved in their DNA replication. It seems reasonable to speculate that the genome size of ssDNA viruses is limited because a single nick in viral DNA will be a fatal disruption of their genome, unlike in organisms whose information is carried in dsDNA. However, some ssDNA viruses are more complex: these include the Nanoviridae, in which the entire genome is composed of 6 to 8 ~1-kb ssDNA segments, each packaged in a separate particle; the Pleolipoviridae, which infect Archaea and contain a single circular ssDNA molecule ranging up to approximately 10 kb in size; and the Bidnaviridae, which infect silkworms and whose genomes consist of a 6 kb and a 6.5 kb DNA molecule, encapsidated separately.

The DNA in these viruses can be either circular or linear; in the latter case, 'hairpin' structures at the ends of the DNA participate in priming of DNA replication (Figure 2(c)). In some ssDNA viruses, either of the two complementary strands can be packaged, so that a virus preparation is a mixture of particles with either strand; in others, only one of the strands is packaged into virions. The DNAs of ssDNA viruses are replicated by a mechanism similar to 'rolling circle' replication, involving synthesis of dsDNA intermediates containing multiple tandem copies of the viral genome. It should be noted that the template for the mRNAs of ssDNA viruses is not the ssDNA that the infecting virion brings into the cell, but rather the dsDNA produced intracellularly in infected cells (Figure 1).

Group III: dsRNA Viruses

The dsRNA viruses form a large and diverse group of viruses. They include the *Reoviridae*, which in turn include rotaviruses, a major cause of morbidity and mortality from childhood diarrhea; rice dwarf virus, and other important plant pathogens; bluetongue virus, an important disease of sheep and other livestock; and several bacteriophages. The L-A 'virus' of *Saccharomyces cerevisiae* is also classified with these viruses, although, unlike authentic viruses, this agent is not released from cells, but spreads from cell to cell during mating of the host.

The genomes of these viruses can be segmented, with anywhere from 1 to 12 dsRNA molecules packaged together in a virion. Each of these RNAs carries the information for only one (or sometimes two) proteins. RNA-dependent RNA polymerase molecules are also present in the particle. The dsRNA genomes cannot, of course, be translated directly, but they serve as templates for production of (+) strand mRNA molecules. In fact, after infection the dsRNAs in the cytoplasm are retained in a subviral particle; the 'progeny' mRNA molecules are extruded from these particles through pores at 5-fold axes of icosahedral symmetry. (As an icosahedron has 12 5-fold axes, this appears to place an absolute limit on the number of genomic RNA segments that can be accommodated in these viruses.) This sequestration of the dsRNA in an intracellular subviral particle may serve to shield this RNA from detection by elements of the innate immune system. Upon release from the subviral particle, the (+) strand mRNAs are translated in the cytoplasm; they are also incorporated into newly assembling subviral particles, where they are copied by the viral polymerase into (−) strand RNAs, thus reproducing the dsRNA genomic RNA of the virus.

Interestingly, in some dsRNA viruses, RNA replication is semiconservative, while in others it is conservative: in other words, in some, both the (+) and (−) strands of the incoming, parental dsRNA are copied, forming progeny molecules that will give rise to new dsRNA (semiconservative replication). In others, the parental (−) strand is copied multiple times, forming multiple (+) strand progeny RNAs; these are the templates, in these viruses, for synthesis of new (−) strand molecules. The former class includes infectious bursal disease virus, an avian dsRNA virus, while the latter includes the reoviruses.

Group IV: (+) Strand RNA Viruses

The (+) strand RNA viruses include a number of familiar pathogens, such as poliovirus; hepatitis C virus; and the common cold virus (rhinovirus). Many plant viruses, including tobacco mosaic virus (the first virus to be crystallized and the first to be reconstituted *in vitro* from its protein and RNA components), are also (+) strand RNA viruses. These viruses are unique in that their genomic RNA is translated immediately upon infection; that is, the virus particle is simply a package that introduces an mRNA molecule into the cell. It is the translation of this RNA, and the resulting synthesis of the virus-specific proteins, that initiates the virus replication process. Obviously, these proteins include the RNA-dependent RNA polymerase that will replicate the genome; as this protein can be produced in the cell from the viral RNA, it does not need to be imported into the cell in the virus particle. These are the only RNA-containing viruses that do not require a polymerase in the particle; not coincidentally, they are also the only RNA viruses in which infection can be initiated if naked RNA is artificially introduced into the cell.

Most (+) strand RNA viruses have relatively small genomes (4–9 kb). However, the largest known RNAs in nature are the genomes of the coronaviruses, which are 27–32 kb in length (Gorbalenya *et al.*, 2006; Sawicki *et al.*, 2007). Some

Figure 3 RNA-dependent RNA synthesis can be primer-independent (*de novo* synthesis) or primer-initiated. Orange lines represent RNA template (3' to 5' direction). Red arrows represent RNA synthesis (5' to 3' direction). Purple circle linked to a red line represents a 5' cap linked to a RNA oligonucleotide. Green-filled shape represents a protein that serves as a primer.

(+) strand genomic RNAs are replicated *de novo*, while others are primed by attachment of the first nucleotide to a viral protein (see Figure 3). Many (+) strand RNA viruses infecting plants have structures resembling tRNAs at the 3' end of their genomes; in fact, in many cases these structures can be acylated *in vitro* by tRNA synthetases. These structures appear to play a variety of roles in virus replication, contributing both to translation initiation and to genome replication.

Group V: (−) Strand RNA Viruses

Many viruses, including influenza, Ebola, and rabies viruses, contain RNAs that are complementary to the mRNAs for the virus-coded proteins. Obviously, these (−) strand viruses must contain RNA-dependent RNA polymerase in order to produce the viral mRNAs upon infection. The total length of their genomes ranges from ~11 kb to ~25 kb, but the genomes are frequently segmented, with individual virions containing anywhere from 2 to 8 RNA molecules which collectively comprise the viral genome. Interestingly, no (−) strand RNA viruses infecting prokaryotes have yet been described.

The virus-coded polymerase in a (−) strand RNA virus must be able to copy the genomic RNA(s) to produce the viral mRNAs; copy the genomic RNA(s) into (+) strand RNAs that will serve as templates for production of new genomes; and copy these (+) strand molecules into new, (−) strand genomic RNAs. In many cases, initiation of synthesis does not require a primer: a single nucleoside triphosphate provides the 3'OH for elongation (*de novo* synthesis, Figure 3). In some (−) strand RNA viruses, such as vesicular stomatitis virus, a single genomic RNA molecule contains as many as 6–7 genes. The polymerase produces the individual mRNAs for these

proteins by copying the genomic RNA, beginning by copying the 3' end and proceeding to the 5' end. However, the transcription is interrupted, stopping at the end of each gene and reinitiating RNA synthesis at the beginning of the next gene. In many cases, the switch in polymerase function from mRNA production to genome replication is governed by the accumulation of one or more virus-coded proteins.

Influenza virus is an orthomyxovirus with a segmented (–) strand RNA genome: the virus particle contains 8 distinct RNAs. The 8 RNAs have common sequences of ~12 bases at both of their ends, flanking the individual coding sequences. The sequences at the two ends of each segment are complementary to each other, and it is thought that they pair with each other, producing a circular topology in the RNA. This paired region appears to be the promoter for synthesis of the templated mRNA. Unlike many RNA viruses, influenza replicates its RNA entirely in the nucleus. The 5' ends of the mature viral mRNAs are obtained by 'cap-snatching,' i.e., physically removing the 5' ends from cellular pre-mRNA molecules (including the cap structure) and extending them with viral coding sequences (Figure 3). The 8 RNAs can produce as many as 12 proteins, as some of the mRNAs copied from the genomic RNA are translated from alternative initiation codons ('leaky scanning,' Figure 4(f)) and others are inefficiently spliced, using the splicing machinery in the nucleus. How the virus ensures that all 8 segments will be packaged into progeny virions is a long-standing, unsolved problem in virology.

One more variation on the theme of (–) strand RNA viruses is provided by 'ambisense' RNA viruses. These include members of the bunyavirus family, such as Rift Valley fever virus, and of the Arenavirus family, such as lymphocytic choriomeningitis virus and Lassa virus. In these viruses, the RNA molecules produced by copying the incoming genomic RNAs are not entirely mRNA, as described above; rather, portions of these RNAs are recopied in the infected cell, forming subgenomic mRNAs of the same polarity as the incoming viral RNA.

Group VI: (+) Strand RNA Viruses with DNA Intermediates

The viruses we now call 'retroviruses,' or more specifically 'orthoretroviruses,' have long excited great scientific interest. They were originally detected very early in the twentieth century by their ability to induce tumors in animals. Most recently, they have been the focus of an extraordinary level of attention, because human immunodeficiency virus (HIV-1), the causative agent of AIDS, is a retrovirus. Human T-cell leukemia virus (HTLV-1), which causes leukemias as well as other diseases, is also a retrovirus.

A retrovirus particle contains two RNA copies of its genome. They are ~8–10 kb in length and are both of the same, (+) strand polarity, and they are joined together into a dimeric structure by a limited number of base pairs (D'Souza and Summers, 2005). When the particle infects a new host cell, the RNA-dependent DNA polymerase or 'reverse transcriptase' in the virus copies this RNA into dsDNA. Although two copies of the RNA are present, the virus is best described as 'pseudodiploid,' as only a single genomic DNA copy is synthesized

during the infection. Reverse transcriptase frequently jumps between the two RNAs while it is making the DNA copy, resulting in recombination: this is an important source of genetic variation in these viruses.

After the DNA is synthesized, it is imported into the nucleus along with some of the proteins from the virus particle, including a second enzyme, 'integrase.' This enzyme catalyzes the insertion of the viral DNA into the chromosomal DNA of the cell. The viral sequences are then replicated as part of the chromosome.

The mechanisms by which the viral genes, now resident in the chromosome, are expressed are similar, although not quite identical, to those of cellular genes. The viral RNA carries, near its 3' end, sequences which are copied into the 5' end of the DNA version of the genome; these sequences include promoters recognized by Pol II. (In other words, the viral genomic RNA includes its own promoter, despite the fact that Pol II promoters are normally outside the transcriptional unit.) Like cellular mRNAs, the transcripts are capped at their 5' ends and polyadenylated at their 3' ends.

Some of these RNA copies are destined to be encapsidated into progeny virus particles, while some are mRNAs for Gag (the building block of the virus particle) and Gag-Pol (a fusion protein containing both Gag and the three virus-coded enzymes, i.e., protease, reverse transcriptase, and integrase). All of these RNAs are full-length, intact copies of the viral RNA that entered the cell in the infecting virus particle; thus, they must be exported to the cytoplasm without being spliced, unlike nearly all cellular Pol II transcripts. However, other virus-coded proteins are made from mRNAs that are formed by splicing the full-length viral transcript (Figure 4(c)). These proteins include the Env protein, which functions in attachment and penetration of progeny virus particles into new host cells. Thus, successful virus replication requires that both spliced and unspliced transcripts, in the proper ratio, be exported to the cytoplasm. Retroviral RNAs contain structures which facilitate their escape from the splicing machinery, ensuring that some unspliced transcripts are sent to the cytoplasm. Some retroviruses, including HIV-1, also encode proteins that participate in this process.

One retrovirus, HTLV-1, produces a protein from mRNAs of the polarity complementary to the viral RNA. These mRNA molecules are transcribed from a promoter at the 3' end of the viral DNA. Thus HTLV-1, unlike other retroviruses, is really an 'ambisense' RNA virus. Remarkably, the same stretch of viral sequence that encodes this protein in the 'antisense' direction is also translated from other mRNA molecules in the 'sense' direction: in other words, both complementary versions of this stretch of the viral genome are translated, producing two completely different proteins.

It is interesting to note that the primer for the first strand of retroviral DNA synthesis from the viral RNA is a tRNA molecule. All retroviral genomes contain an 18-base stretch, called the 'primer-binding site,' that is complementary to the 3' 18 bases of a cellular tRNA. Different retroviruses use different tRNAs as primers. The tRNA is annealed to the primer-binding site before or during the assembly of the virus particle; the Gag protein is a highly active nucleic acid chaperone and unwinds the tRNA, making the annealing possible (Rein, 2010).

Figure 4 Viral translation strategies. (a) polyprotein synthesis, (b) segmentation of viral genome, (c) production of multiple mRNAs, (d) IRES and termination–reinitiation, (e) inefficient suppression of termination, and (f) leaky scanning. Red and orange wavy lines represent RNAs in the 5' to 3' and 3' to 5' direction, respectively. Solid purple rectangles represent protein products. Blue-filled shapes represent ribosomes. '+ ssRNA-RT' refers to RNA-containing viruses that produce a DNA intermediate in the cell.

The genomic RNA is chemically identical to the mRNA for Gag and Gag-Pol. (Although it has often been suggested that the incoming viral RNA is translated upon infection, there is no definitive evidence that this occurs.) While these RNAs have identical sequences, recent research indicates that they have crucial differences in secondary and tertiary structure. Specifically, dimerization entails changes in the secondary structure of each monomer, as well as the formation of new, inter-molecular base pairs. These changes evidently produce

structures in the RNA that are recognized by the Gag protein, leading to the highly selective packaging of genomic RNA. In fact, there may be two distinct pools of full-length viral RNA in the virus-producing cell: monomers being translated into Gag and Gag-Pol, and dimers destined for encapsidation.

There are six genera of orthoretroviruses, and it is important to recognize the diversity within this family of viruses. Their replication mechanisms and interactions with their host cells are quite different from one genus to another. While a cell

infected with HIV-1 usually dies within a few days after infection, cells productively infected with murine leukemia viruses or avian leukosis viruses almost never die.

It should also be noted that an astonishingly large fraction (~40%) of the sequences in our own DNA comes from RNA, as a result of infections of germline cells with retroviruses or the action of intracellular elements called retrotransposons. Some of these latter elements are remarkably similar to retroviruses, except that there is no extracellular phase in their life-cycle, while others are much more divergent.

Group VII: dsDNA Viruses with RNA Intermediates

There are three families of viruses in which the virion contains DNA, but this DNA is produced in the virus-producing cell by reverse transcription of an RNA intermediate. In essence, this replication scheme is a permutation of the retroviral replication cycle, such that reverse transcription precedes, rather than follows, the release of the virus from one cell and its entry into another. These three families are the Spumaretroviruses or 'foamy viruses,' the hepadnaviruses, and the caulimoviruses. The spumaretroviruses are endemic in many species of primates, but are not known to be associated with any diseases. The prototypical hepadnavirus is hepatitis B virus, an extremely important public health problem associated with hepatocellular carcinogenesis as well as liver cirrhosis. The caulimoviruses are plant viruses exemplified by cauliflower mosaic virus. In these viruses, as in orthoretroviruses, genetic information is continually cycled between DNA and RNA during virus replication; however, there are striking differences between them.

Spumaretroviral genomes are roughly the same size as orthoretroviral genomes (~9–11 kb), and there is close analogy between the genes and many aspects of the replication of these two virus families. One important similarity between orthoretroviruses and spumaretroviruses is that in both, the DNA is inserted by the viral integrase into the chromosomal DNA of the host cell.

In contrast, hepadnaviruses are far smaller and simpler, with genomes of only ~3 kb. (They are not quite as simple as this suggests, as more than half of the genome is translated in more than one reading frame.) Virions contain dsDNA in which the (–) strand is covalently closed while there are gaps in the (+) strand. Upon infection, the DNA enters the nucleus and the gaps in the (+) strand are repaired. Integration of this dsDNA is not necessary for virus replication; rather it is maintained and replicated as an unintegrated circular DNA in the nucleus. (On the other hand, hepatocellular carcinomas in infected humans and animals frequently contain integrated DNA copies of the viral genome; their role in tumorigenesis is not clear at this time.) Transcripts are exported to the cytoplasm, where the virus-coded reverse transcriptase copies them into DNA that will be encapsidated. The first DNA strand to be synthesized (the (–) strand) is primed from a tyrosine residue within the reverse transcriptase protein.

The caulimoviruses infect plants. Virus particles contain DNA with gaps in both strands. Remarkably, one of the virus-coded proteins induces the ribosomes to initiate translation on internal AUG codons in the viral RNA.

Gene Expression Strategies of RNA Viruses

In general, mRNAs in eukaryotic cells are translated beginning at the first AUG initiation codon; as virtually all viruses encode more than one protein, RNA viruses must possess a mechanism for production of multiple proteins from the RNA genome. Different viruses have a wide variety of solutions to this problem. These include: (1) translation of the genome into a single, large 'polyprotein' that is cleaved post-translationally into the mature proteins that function in virus replication (Figure 4(a)). Both hepatitis C virus (a flavivirus) and poliovirus (a picornavirus) use this mechanism. (2) segmentation of the viral genome: it consists of several discrete RNAs, each encoding one (or two) of the required proteins (Figure 4(b)). A number of (+) strand RNA viruses infecting plants (e.g., brome mosaic virus) and insects (e.g., flock house virus) use this strategy, as do orthomyxoviruses such as influenza and dsRNA viruses such as reoviruses. (3) production of multiple mRNAs (Figure 4(c)). For example, the alphaviruses (e.g., Sindbis virus) are (+) strand RNA viruses whose incoming viral RNA is translated at the outset of the infection. However, the (–) strand produced by copying the viral RNA contains one or more internal promoters for the viral RNA-dependent RNA polymerase. Thus, the RNAs produced during replication include not only full-length (+) and (–) strand copies of the genome, but smaller RNAs of (+) strand polarity, representing only a portion of the genomic sequence, that will also serve as mRNAs. In a somewhat analogous strategy, coronaviruses produce a nested series of mRNAs encoding different viral proteins. (4) the presence in the genome of a special RNA structure, the 'internal ribosomal entry site' or IRES (Figure 4(d), left panel; Fraser and Doudna, 2007; Martinez-Salas *et al.*, 2008). An IRES obviates the requirement for the 5' cap structure in initiation of translation. In many viruses, it is located near the 5' end of the viral RNA, and functions principally in protecting the viral mRNA from the inhibitory effects that the virus exerts upon normal, 5' cap-dependent translation of host mRNAs. However, in some viruses including cricket paralysis virus, an IRES in the interior of the viral RNA allows translation of an internally placed open reading frame (Figure 4(d), bottom left). IRES elements derived from viral genomes have been extremely useful in the design of vectors for simultaneous expression of two genes from a single mRNA. A somewhat analogous mechanism is called termination–reinitiation: here the AUG of a second open reading frame in the RNA overlaps the termination codon of a first reading frame within the 5-base sequence UAAUG (Figure 4(d), right panel). Initiation at this AUG is dependent upon a special sequence placed 5' to this junction. Termination–reinitiation is used in (+) strand RNA viruses such as caliciviruses, dsRNA viruses, and (–) strand viruses. (5) inefficient suppression of the termination codon at the end of an open reading frame, so that some ribosomes continue translating past the termination codon (Figure 4(e)). These ribosomes produce a fusion protein, containing some or all of the sequence encoded 5' of the termination codon and, in addition, the sequence 3' of this codon. The suppression can either be by inefficient translation of the termination codon as an amino acid (as in alphaviruses) or by ribosomal frame-shifting at a site 5' of the termination codon (as in

coronaviruses). Both of these mechanisms are also used by retroviruses (Hatfield *et al.*, 1992). Successful virus replication in these cases requires the optimal efficiency of suppression, yielding the proper ratio of extended to terminated translation products. This ratio is often in the range of 1:10. In some retroviruses, there are two successive frameshift sites, resulting in the production of three proteins from the same mRNA molecule. (6) 'leaky scanning,' in which some ribosomes initiate translation at the 5'-most AUG on an RNA, while others bypass this AUG and initiate at a downstream AUG (Figure 4 (f)). The efficiency of utilization of the AUGs is largely governed by their surrounding sequence contexts. In some retroviruses, the viral RNA contains a CUG in an excellent context for initiation, with an AUG further downstream in the same reading frame; both of these codons are used for initiation, resulting in the production of two protein species, identical except for an N-terminal extension on one of them.

It is important to note that these diverse mechanisms for gene expression are not mutually exclusive: many viruses use more than one of these strategies.

Concluding Remarks

As far as we know, all living organisms are hosts to viruses. We have attempted here to briefly indicate the amazing diversity of information-transmission mechanisms found among viruses. Indeed, it is striking that viruses exhibit far more diversity in this regard than do cellular organisms, whose genomes are exclusively dsDNA. However, all viral genomes larger than those of coronaviruses are also composed of dsDNA. Perhaps this is because dsDNA is more resistant than other nucleic acids to the vicissitudes of mutation and chemical and physical damage. In any case, the study of viruses can only inspire wonder at the unimaginable variety found among living things.

Note on Sources

The primary literature on viral nucleic acids is massive. We have cited a few reviews here, but two textbooks (Flint *et al.*, 2009; Knipe and Howley, 2013) are excellent sources of information. In addition, the website (See Relevant Website – ViralZone) is an invaluable resource. We apologize to the many researchers whose results we have summarized without attribution here.

Glossary

A, P, and E sites Physical locations on the surface of the ribosome that are occupied by aminoacyl-, peptidyl-tRNA, and deacylated tRNA.

Elongation (of protein synthesis) The sequential steps that lead to the addition of one amino acid at a time to the growing polypeptide chain.

Elongation Factor (EF) A non-ribosomal protein that facilitates the process of elongation only. (Note: eukaryotic elongation factors are designated eEF where the lower case 'e' signifies 'eukaryotic'.)

Initiation (of protein synthesis) The required steps that lead to the placement of the initiator tRNA in the P site of the ribosome, correctly base paired with the initiating AUG codon.

Initiation Factors(IF) A non-ribosomal protein that facilitates the process of initiation. (Note: eukaryotic

initiation factors are designated eIF where the lower case 'e' signifies 'eukaryotic'.)

Protein synthesis The process of joining amino acids in a specific sequence through the α carbonyl and α amino groups via a peptide bond that is templated by an mRNA molecule.

Ribosome recycling The process of splitting of post-termination ribosomes into subunits and release of mRNA and deacylated tRNA, thereby making available ribosomal subunits for the subsequent rounds of initiation/translation.

Termination (of protein synthesis) The codon-directed (UAA, UAG, or UGA) process of cleavage (and therefore, release) of the polypeptide chain from the tRNA in the P site of the ribosome.

Components of Protein Synthesis

The general dogma established some 40–50 years ago said that 'DNA makes RNA makes protein.' Although this general view has become considerably more complex, the basic components associated with the process of converting RNA into protein have remained the same, Transfer RNA (tRNA), messenger RNA (mRNA), ribosomes, and translation factors. These essential components are discussed below.

tRNA

In the process of converting the linear nucleotide sequence information in an mRNA into amino acid sequence information, an adapter is used to convert the three nucleotide genetic code into a single amino acid, tRNA. The genetic code is nearly

universal, meaning that the majority of organisms from all kingdoms use the same codons to specify the incorporation of the same amino acid into a synthesized polypeptide. As there are 61 different code words (or codons; 61 out of the 64 possible codon combinations) that specify one of the 20 'standard' amino acids incorporated into polypeptides during protein synthesis, a large number of tRNAs exist in cells to allow for the optimal decoding of an mRNA. The requirement of tRNA molecules reflects two basic needs, the carrier of an activated amino acid and a matching of an amino acid with the correct codon in the mRNA. In general, the activation of an amino acid can be described by the following series of reactions (see [Figure 1](#); reviewed in [Yadavalli and Ibba, 2012](#)).

In the first step of the reaction, the amino acid is activated by the formation of an acid anhydride bond between its carboxylic acid and the phosphate of AMP, thus preserving the

Figure 1 Aminoacylation of tRNA – this figure shows the three steps of aminoacylation with the activation of the amino acid (step 1), the transfer of the activated amino acid to the cognate tRNA (step 2) and the normal physiologic splitting of the pyrophosphate into 2 inorganic phosphate molecules (step 3). This final step pulls the reaction in the direction of aminoacyl-tRNA formation and is aided by the subsequent formation of the elongation ternary complex of eEF1A•GTP•aminoacyl-tRNA.

high energy bond that originally existed in ATP. In the second step, the transfer of the activated amino acid to the tRNA, the high energy is preserved through an inductive affect that results from the neighboring 2' (or 3') hydroxyl group.

The ability of the tRNA to serve as an adapter (between the amino acid and the nucleic acid sequence in the mRNA) is the critical component in translation, the conversion of nucleic acid sequence information into amino acid sequence information. This is facilitated based upon the observation that the recognition of the nucleic acid sequence in an mRNA is affected by base pairing with the anticodon loop of the tRNA. However, the geometry of this pairing is not identical to Watson–Crick base pairing as the 3' nucleotide in the codon does not form a perfect Watson–Crick base pair and thus there is 'wobble' in the recognition (Crick, 1966). The 'Wobble Rules' are:

Nucleotide in the 5' position of the anticodon	Nucleotide in the 3' position of the codon
U	A, G
C	G
A	U
G	U, C
I	U, C, A

mRNA

The mRNA is a direct transcript of the genetic information or DNA in that the sequence information is maintained in nucleic acid sequence (although in eukaryotes, some of this information is spliced out). In general, an mRNA is described as having a 5' UTR (untranslated region), a coding region (made of codons of three nucleotides) and a 3' UTR. In both prokaryotes and

eukaryotes, the initiating code word is AUG (with few exceptions from the universal or standard rule) and the terminating code words are UAA, UAG, and UGA (which are recognized by specific protein factors and for which there is no corresponding aminoacyl-tRNA). It should be noted, however, that the so-called 21st (Selenocysteine (Sec)) and 22nd (pyrrolysine (Pyl)) amino acids that have been recently found to be incorporated into proteins during protein synthesis are encoded by codons that normally function as stop signals. Sec is incorporated via a UGA codon and Pyl is inserted by a UAG codon. So far, Sec and Pyl are the only known additions to the pool of 20 universal/standard amino acids. The mechanism of Sec incorporation is quite well understood and requires the presence of the so-called selenocysteine insertion sequence (SECIS) element, a specific structural RNA element present in mRNA (Bellinger *et al.*, 2009; Driscoll and Copeland, 2003). The mechanism of Pyl incorporation is known in less detail (Dinman, 2012). Both mechanisms require the specific Sec-tRNA^{Sec} and Pyl-tRNA^{Pyl}, responsible for decoding of the respective stop codons. Both prokaryotic and eukaryotic systems initiate translation of the majority of their mRNAs with a methionyl-tRNA species (where in bacteria, the amino nitrogen in methionine is formylated) and perform elongation with methionine using a separate methionyl-tRNA. These two species of methionyl-tRNA are differentially recognized by either initiation factors or elongation factors. This ensures that there will be independent supplies of the methionyl-tRNAs, both for initiation and elongation.

The initiation step is important as it establishes the reading frame. But which AUG? In both bacterial and eukaryotic systems, a second element comes into play that distinguishes the initiating code word. In the bacterial system, there is a conserved nucleic acid sequence 5' of the initiating AUG that is complimentary to the 3' end of the rRNA in the small ribosomal subunit (16S) and is 4 to 7 nucleotides upstream (referred to as the 'Shine–Delgarno sequence'; Shine and Delgarno, 1975). In eukaryotic mRNAs, it is (as a rule) the AUG that is closest to the 5' end of the mRNA that is recognized.

Ribosomes

Ribosomes are the catalytic ribonucleoprotein particles on which protein synthesis occurs. Their general composition is as described below (Melnikov *et al.*, 2012):

Bacteria	Eukaryotes
30S subunit	40S subunit
16S rRNA	18S rRNA
~ 20 proteins	~ 30 proteins
50S subunit	60S subunit
5S rRNA	5S rRNA
23S rRNA	5.8S rRNA
	26–28S rRNA
~ 30 proteins	~ 50 proteins
MW = 2.3×10^6	MW = $3.3 - 4.3 \times 10^6$

Of the total mass of the ribosome from either bacteria or eukaryotes, the ribosome is roughly 50% RNA and 50%

protein. Prokaryotic ribosomes on average usually contain slightly less protein (35–45%) than RNA. In spite of this distribution, much of the actual surface of the ribosome is RNA. Thus, the recognition of particular positions on the ribosome by translation factors is often guided by contacts between both protein and rRNA.

If one follows the development of the rRNA from bacteria to eukaryotes, one finds all the ancestral parts in the eukaryotic ribosome with insertions at various points within the linear rRNA sequence. Thus the overall folding of the rRNA and the shape of the bacterial and eukaryotic ribosomes are quite similar. In spite of this similarity, bacterial translation factors do not function on eukaryotic ribosomes and eukaryotic factors do not function on bacterial ribosomes.

Eukaryotic Translation Factors

Listed below are all the translation factors that participate in eukaryotic protein synthesis at the level of initiation (eIF, eukaryotic initiation factor), elongation (eEF, eukaryotic elongation factor) or termination (eRF, eukaryotic release factor). Historically, these proteins were named ‘factors’ as they facilitated binding reactions but may or may not have been associated with an enzymatic process, the making or breaking of a covalent bond.

Name	Molecular weight ^a	Function
eIF1	15000	Accuracy in start site selection, Pi release from eIF2
eIF1A	15000	Accuracy in start site selection
eIF2	125000	Forms ternary complex with GTP and Met-tRNA ^{iMet}
eIF2A	67000	Suppresses IRES-mediated translation
eIF2B	260000	Facilitates GTP exchange for eIF2•GDP
eIF2D	65000	Mediates ribosomal recruitment of Met-tRNA ^{iMet} in a GTP-independent manner within minor pathways
eIF3	650000	Provides the free pool of 40S subunits for initiation
eIF4A	45000	ATP-dependent RNA helicase
eIF4B	160000	Stimulates eIF4A and eIF4F activities
eIF4F	250000	Recognizes m ⁷ G cap, unwinds RNA
eIF4H	25000	Stimulates eIF4A and eIF4F activities
eIF5	65000	Stimulates GTP hydrolysis in the ternary complex
eIF5A	15000	Activates peptide bond formation from the E site
eIF5B	125000	GTP-dependent subunit joining
eEF1A	50000	Forms a ternary complex with GTP and aa-tRNA
eEF1B	110000	Stimulates GDP exchange of eEF1A•GDP
eEF2	100000	Drives translocation using GTP
eEF3	116000	ATPase, required for elongation (in fungi only)
eRF1	47000	Recognizes stop codons UAA, UAG, UGA
eRF3	75000	Binds eRF1, binds and hydrolyzes GTP
ABCE1	65000	Uses ATP to recycle ribosomes
DHX29	155000	Promotes scanning on mRNAs with highly structured 5' UTRs
Ded1	66000	Promotes scanning in yeast <i>Saccharomyces cerevisiae</i>
PABP	71000	Facilitates recruitment of recycled 40S subunits to the 5' end of mRNA via mRNA circularization

^aAggregate molecular weight: eIF2, eIF2B, eIF3, eIF4B, eIF4F, and eEF1B are multisubunit proteins.

When one considers the relative amounts of most of the components in the translation system, the rough numbers come out as follows:

1 ribosome: 0.3–1.0 initiation factors and eEF2; 8–10 aminoacyl-tRNAs: 20–30 eEF1A: 0.1–0.2 mRNAs (encoding a 50 000 molecular weight protein).

The relatively large excess of eEF1A ensures that all of the aminoacyl-tRNA is present in the cell as a ternary complex (eEF1A•GTP•aminoacyl-tRNA) ready to participate in protein synthesis. This is also true for the initiating methionyl-tRNA as there is a molar excess of eIF2. Additionally, complexes of the aminoacyl-tRNA with either eEF1A or eIF2 stabilize the aminoacyl linkage to extend the half life of the chemical bond approximately 5-fold over free aminoacyl-tRNA.

Cap-Dependent Protein Synthesis, the Predominant Pathway

Approximately 90% of the mRNAs within eukaryotic cells are translated via the ‘cap-dependent pathway’ (Aitken and Lorsch, 2012; Hinnebusch, 2011; Jackson *et al.*, 2010; Merrick, 2003). Simply put, the mRNA’s m⁷G cap and neighboring nucleotides are bound to a 40S subunit containing bound ternary complex. Subsequent movement of the mRNA (scanning) along the 40S subunits leads to the recognition of the AUG start codon via the anticodon of the Met-tRNA^{iMet} in the ternary complex. This is followed by subunit joining.

This process has been broken down into considerably greater detail, both mechanically (when proteins are bound or released from the 40S subunit) and kinetically (where are the slow/rate limiting steps). Figure 2 presents a useful pathway that reflects the more detailed mechanics of eukaryotic initiation (Merrick, 2010). As with bacteria, the eukaryotic ribosomal subunits tend to associate forming inactive 80S ribosomes that are in equilibrium with 40S and 60S subunits. The binding of eIF3 (and eIF1 and eIF1A) to the 40S subunit shifts the equilibrium to 40S subunit complexes and this serves as the original pool of 40S subunits on which to build an initiation complex. The next step is the addition of the ternary complex (eIF2•GTP•Met-tRNA^{iMet}) to the 40S complex, a reaction facilitated by the interaction of the ternary complex with both the 40S subunit and eIF3.

To go further in the pathway requires the addition of mRNA. In eukaryotic cells with the synthesis and processing of the mRNA in the nucleus, the molecule that enters the cytoplasm is an mRNP which is about 50% protein and 50% RNA. In order to bind the 5' end of the mRNA to the 43S complex, the 5' end needs to be single stranded and absent of protein so that the RNA strand can be bound into the 43S mRNA channel. The conversion of the mRNP into an mRNA suitable for binding to the 43S complex is a process referred to as ‘activation’ and requires eIF4A, eIF4B, and eIF4F and ATP. It is the helicase activity of eIF4A, a DEAD-box helicase, that accounts for this conversion although the relative contribution of eIF4A versus eIF4F (a three subunit protein composed of eIF4A, eIF4E, and eIF4G) is unknown. When examined *in vitro*, eIF4F is a more rigorous helicase and therefore has been assumed to be the predominant protein responsible for the activation

Figure 2 80S initiation complex formation – formation of an initiation complex as seen for the attachment of the first ribosome to an mRNA. Steps 1 through 6 are involved in the synthesis of the 80S initiation complex, ready to enter the elongation phase of translation. Steps 7 and 8 represent the recycling steps and these are the steps subject to global regulation via protein phosphorylation. Adapted from Merrick, W.C., 2010. Eukaryotic protein synthesis: Still a mystery. *Journal of Biological Chemistry* 285, 21197–21201 and used with permission of the Journal of Biological Chemistry.

process. In addition, the association of eIF4F with the mRNA helps in the binding of the mRNA to the 43S subunit via a protein–protein interaction with eIF3.

Once the mRNA is associated with the 43S complex, making it a 48S complex, the process of scanning begins where the mRNA is inspected in a 5′ to 3′ direction in search of the initiating AUG codon. This process requires ATP and for most mRNAs, eIF4A is sufficient to locate the start codon. More recent experiments have implicated several other DEAD-box helicases in the process of scanning as a requirement for the optimal expression of proteins encoded by mRNAs that have either long 5′ UTRs or 5′ UTRs with extensive secondary structure (Pisareva *et al.*, 2008).

The sensing of the initiating AUG codon is performed by the anticodon of the Met-tRNA^{Met} and this accounts for the highly specific recognition of the AUG codon (Cigan *et al.*, 1988). However, this does not account for the finding that the optimal start codon context is A/GXXAUG (Kozak, 1986). The preference for a purine at the minus 3 position (the A in AUG is nucleotide +1) reflects an interaction with the α subunit of eIF2 (Pisarev *et al.*, 2006). In mammalian systems, it was also noted that often the presence of a G following the AUG provided a preferred context. However, this interpretation is not entirely straight forward. In the synthesis of proteins, the N-terminal methionine is often a subject to co- and posttranslational modifications (Jha and Komar, 2011), i.e., deformylation in bacteria and removal in both prokaryotes and eukaryotes, which is expected to occur in about half of all synthesized proteins and depending on the final amino terminus (which amino acid, is it N-acetylated), the protein may be stable or quite labile (sensitive to proteasome degradation). Thus, in the absence of data relating to the half life of the protein, the actual preference for nucleotides 3′ of the initiating AUG must be more carefully investigated.

With the correct start codon identified, there is hydrolysis of the GTP in the ternary complex (if this has not already happened), release of eIF1 and release of the phosphate bound to eIF2 (Nanda *et al.*, 2009, 2013). The release of the phosphate drives the release of the eIF2•GDP complex. Subsequent binding of eIF5B•GTP allows for subunit joining with the 60S subunit and the correct placement of the Met-tRNA^{Met} in the P site. At present, the release of the factors associated with the early steps of initiation (eIF1, eIF1A, eIF3, eIF4A, B or F, and eIF5) has been accomplished with the release of eIF1 or at the latest, with the release of the eIF2•GDP complex. Retention of the other initiation factors on the 40S subunit blocks subunit joining and the completion of the initiation process.

While the above steps have led to an initiation complex prepared to form the first peptide bond, there are two steps that are not included for the full catalytic use of the initiation factors. The first is the recycling of eIF2. As a classic G protein, eIF2 exits the initiation pathway as an eIF2•GDP complex. To re-enter the pathway the bound GDP needs to be exchanged for GTP and this requires the protein complex termed eIF2B. As seen in step 7 of Figure 2, eIF2B accomplished the exchange for GTP made necessary by the very tight binding of GDP by eIF2, $K_d = 10^{-8}$ M, compared to the looser binding of GTP, $K_d = 10^{-6}$ M. Once the GDP is exchanged, the eIF2•GTP complex can then rebind Met-tRNAi.

In a similar manner, during the process of initiation the subunits of eIF4F come apart and then need to be reassembled although the precise time and place for the disassembly is not known. Given the ability of eIF4G to bind either eIF4E or eIF4A, it is likely that the reassembly process would allow for the initial binding of either eIF4A or eIF4E with the other subunit binding subsequently.

Both of the recycling steps, for eIF2•GDP and the reassembly of eIF4F, are the major points for global regulation via various protein kinases and this regulation will be discussed in greater detail below. However, the mechanistic outcome of this regulation depends on the process (Merrick, 2003). When down regulation is affected by eIF2 α phosphorylation (on Ser51), the reduction in the level of ternary complexes (eIF2•GTP•met-tRNA^{Met}) tends to reduce the translation of the majority of mRNAs equally, with the exception of a few mRNAs that use alternative ways or codons to initiate translation. In contrast, down regulation of the level of eIF4F activity through 4E-BP drives mRNA competition such that poorly translated mRNAs may be completely silenced while only a modest reduction in expression is seen for the efficiently translated mRNAs (perhaps only a reduction of 10 to 20%).

Other Initiation Events

Although cap-dependent translation is the most common form, a reasonable number of mRNAs contain internal ribosome entry sites (IRESs) which allow for the direct binding of the 40S subunit at or near the internal initiating AUG (Komar *et al.*, 2012; Thompson, 2012). This 40S subunit may or may not already have a bound ternary complex and/or eIF3. The differential requirement for initiation factors depends on the mRNA and is best characterized by viral IRES elements which may require all of the initiation factors except eIF4E (poliovirus), all of the initiation factors except the mRNA specific ones (eIF4A, eIF4B, and eIF4F; hepatitis C virus) or none of the initiation factors (cricket paralysis virus). Although not proven, it would appear that most cellular IRES-containing mRNAs likely require all of the initiation factors except eIF4E.

IRES elements are generally characterized by being GC rich, having more extensive secondary structure and containing several hundred nucleotides in the 5′ UTR relative to the mRNAs that use the cap-dependent pathway. For what few structures are known by cryo-EM, the IRES element is commonly found bound to the equivalent location of the E site of the ribosome and it is this association that facilitates the binding of the mRNA in the absence of binding of the m⁷G cap and scanning as described above. However, the binding of the mRNA in this fashion does not preclude that subsequent scanning of the IRES-containing mRNA might also occur.

Cap-dependent and IRES-mediated translation appear to account for 95 to 99% of cellular translation. Other rare initiation events include shunting (Yeuh and Schneider, 2000), re-initiation (Hinnebusch, 2011), cap-dependent internal initiation (Shatsky *et al.*, 2010), initiation with short 5′ UTRs (TISU or translation initiation of short 5′ UTRs) (Dikstein, 2012), and RAN translation (repeat associated, non-AUG) (Zu *et al.*, 2011) are also known to occur, but the mechanism by

Figure 3 Elongation, termination, and ribosome recycling – shown above is the movement of an 80S initiation complex into the elongation cycle which uses sequentially eEF1A•GTP•aminoacyl-tRNA, the peptidyl transferase center of the ribosome and eEF2•GTP. These three steps are then repeated until a termination codon is reached (UAA, UAG, or UGA). When a stop codon is reached, the complex of eRF1•eRF3•GTP recognizes the stop codon and triggers the release of the polypeptide chain from the tRNA in the P site. The resulting ribosome complex is then recycled in an ATP-dependent manner by ABCE1 which drives the release of the mRNA and tRNA. This process is stimulated by the presence of eIF3 which helps to begin the next initiation event. As in initiation, eEF1A•GDP requires a recycling protein to regenerate eEF1A•GTP which can then rebound an aminoacyl-tRNA.

which these events happen remains understudied and poorly described. As such, they will not be described in further detail within this review.

The Elongation Cycle

The completed initiation complex contains the initiating Met-tRNA^{Met} in the P site and has an exposed codon in the A site. The next step in translation is the forming of a ternary complex of eEF1A•GTP•aa-tRNA^{aa} which can then bind to the A site codon in response to the standard use of the genetic code (where a specific triplet in the mRNA corresponds to only one aa-tRNA; see Figure 3). The correct selection of the aa-tRNA resides in two steps, one where the GTP might be hydrolyzed to stabilize the complex and allow the release of either the eEF1A•GDP•aa-tRNA^{aa} from the ribosome or the release of eEF1A•GDP with an imperfectly paired aa-tRNA^{aa} in the A site that is then subsequently lost. The key to the correct selection is the conformational change in the ribosome that takes place

with the correctly paired aa-tRNA and adds several additional hydrogen bonds for stabilization (thereby explaining the difference in stability of the correctly vs. the incorrectly paired aa-tRNA in the A site).

As perhaps the fastest step in the elongation cycle, correctly paired aa-tRNA in the A site immediately undergoes condensation with the Met-tRNA^{Met} to form a peptide bond on the tRNA in the A site. The chemistry of this reaction appears to be the nucleophilic attack by the amino group of the A site aa-tRNA aided by the 2' hydroxyl of the 3' terminal adenosine of the tRNA. With peptidyl-tRNA bound in the A site and a free tRNA in the P site, the next step is to move the mRNA by one codon's worth to be able to extend the growing polypeptide chain by another amino acid. Here eEF2•GTP binds to the A site of the ribosome and with hydrolysis of the GTP triggers a conformational change that moves the peptidyl-tRNA into the P site and the free tRNA into the E site. This exposes a new codon in the A site of the ribosome and thus allows the elongation cycle to continue. It has been noted that experimentally, the accuracy of matching the incoming aa-tRNA with

the A site codon is enhanced by having the free tRNA in the E site and that the so-called translocation (movement of the ribosome from one codon to another) is occurring through a number of substeps, which are not discussed here for simplicity. With each subsequent binding of an aminoacyl-tRNA to the A site, there is the release of the free tRNA from the E site. Thus, there are at least two tRNAs associated with the ribosome at all times post initiation.

Not pictured in the elongation cycle is the protein eIF5A originally identified as stimulating methionyl-puromycin synthesis, a model initiation assay. Current structural information indicates that eIF5A binds in the vicinity of the E site on the ribosome and biochemically, this enhances the rate of peptide bond formation between an aminoacyl-tRNA or peptidyl-tRNA in the P site with an aminoacyl-tRNA in the A site. While the extent of increase in the elongation rate may only be about 2-fold, for stretches of polyprolines (at least three), the requirement for eIF5A becomes nearly absolute (Buskirk and Green, 2013; Gutierrez *et al.*, 2013). From the databases, it would appear that most eukaryotes (i.e., humans) contain about 7000 different proteins with at least three prolines in a row which may account for the essential nature of eIF5A (Pell *et al.*, 2013).

As was observed in the initiation pathway, eEF1A is also a G protein with an approximate 100-fold preference for GDP over GTP. As a consequence, a GTP exchange factor is required, eEF1B. In this manner, eEF1A•GDP is converted to eEF1A•GTP which can then bind a new aminoacyl-tRNA to form the ternary complex eEF1A•GTP•aa-tRNA^{aa} and continue to participate in protein synthesis. Perhaps curiously, although eEF2 is also a protein that uses GTP for the translocation step, it has the 'more usual' higher affinity for the substrate GTP than the product GDP and thus no recycling protein is required for eEF2.

In bacterial systems, it has been estimated that in log phase growth, approximately 60% of the cellular energy is devoted to protein synthesis. Equivalent amounts of energy may also be devoted to protein synthesis in log phase growth of single cellular eukaryotes or cells in tissue culture. This large expenditure of energy is the result of the requirement for 4 high energy phosphates for each peptide bond formed (aminoacylation, 1 ATP → AMP + PPi → 2 Pi; elongation, 2 GTP → 2 GDP + 2 Pi) as the amount of energy associated with initiation (2 GTP → 2 GDP + 2 Pi, some small number of ATPs to ADPs) or termination (1 GTP → 1 GDP + 1 Pi, 1 ATP → 1 ADP + 1 Pi) is quite small by comparison as each of these events only happens once.

In yeast, however, an additional fungi-specific elongation factor eEF3 is required to facilitate release of deacylated tRNA from the E site in an ATP-dependent manner, thereby allowing binding of the next aminoacyl-tRNA to the A site (Chakraburty, 2001; Andersen *et al.*, 2006). Therefore, in yeast the translation process is even more energy consuming. eEF3 is an essential protein and is required for each cycle of translation. It is unclear why translation in yeast requires eEF3, but translation in bacteria or higher eukaryotes does not. The requirement for eEF3 resides in the yeast ribosome as mammalian ribosomes do not require eEF3 when using yeast eEF1A and eEF2 as the elongation factors. No eEF3 homologs can be found in genomes of other organisms. Comparison of the

yeast and bacterial ribosomes does not reveal any particular structural features that would indicate the need for eEF3 in case of yeast elongation cycle. Thus, at present the evolutionary origin of eEF3 and its requirement remain rather enigmatic.

Termination of Translation and Ribosome Recycling

At the end of the coding region is one of three termination codons (UAA, UAG, or UGA). In all of translation, this is the one time that the nucleotide sequence is recognized by a protein, eRF1 (Dever and Green, 2012; Shoemaker and Green, 2011). The complex of eRF1•eRF3•GTP binds to the A site of the ribosome in response to a stop codon in the A site (see Figure 3). The binding of just eRF1 is sufficient to trigger the hydrolysis of the aminoacyl linkage to the tRNA in the P site thus releasing the growing polypeptide chain from its tethered position. However, *in vivo*, it is thought that this event is coupled with the hydrolysis of GTP in eRF3 so that release of the growing polypeptide chain and separation of eRF1 and eRF3 occur at nearly the same time.

Unfortunately, the product, a ribosome with a bound mRNA and unacylated tRNAs in the P and E sites, is relatively stable. To promote the recycling and reuse of the ribosome, following peptide release the protein ABCE1 binds and in the presence of ATP (and eIF3), drives the dissociation of this complex into its individual parts (Pisarev *et al.*, 2010). This is enhanced by the presence of eIF3 as its binding to the 40S subunits prevents possible reassociation with the 60S subunit (as was observed in initiation; see Figure 2). ABCE1 is essential and highly conserved in eukaryotes and archaea.

Protein Synthesis Beyond the First Ribosome

The pathways shown in Figures 2 and 3 provide the mechanisms for the synthesis of a protein from the first binding ribosome. In actuality, mRNAs generally are bound by 3 to 5 ribosomes and this complex is referred to as a polysome. This reflects the general observation that mRNAs can be initiated while there is still a ribosome attempting to complete the synthesis of the encoded protein. In general, it appears that ribosomes that are released at termination begin the initiation process more efficiently. In part, this is because that in log phase growing cells there is a shortage of free 40S subunits as these appear to be participating in elongation. However, there is also an element of intramolecular interaction that is facilitated by the circularization of the mRNA bringing the 3' end of the mRNA in proximity of the 5' end of the mRNA. This is achieved through physical interactions of the poly(A) binding protein (PABP) at the 3' end with eIF4F at the 5' end of the mRNA. This 'intramolecular effect' yields 40S subunits at termination that are 3 to 10-fold more likely to begin a new series of steps in the initiation pathway than is a free 40S subunit. In model systems, this accounts for much of the loss of translational efficiency when the poly(A) tail is omitted and hence there is no PABP at the 3' end of the mRNA.

Molecular Mimicry

The primary element bound in the P site of the ribosome is either aminoacyl-tRNA or peptidyl-tRNA. In contrast, binding to the A site can involve eEF1A•GTP•aminoacyl-tRNA, eEF2•GTP, eRF1•eRF2•GTP or ABCE1•ATP. Yet three of these complexes lack nucleic acid. From three dimensional structures, both eRF1 and a domain of eEF2 have a protein projection that takes on the appearance of the anticodon stem and loop (negatively charged) and for eRF1 an amino acid sequence that recognizes the stop codons through hydrogen bonding in a manner similar to nucleotides. This ability of a protein domain to be a mimic of the anticodon stem and loop has been referred to as molecular mimicry (Nissen *et al.*, 1995).

Mistakes in Translation

There are two different sites where mistakes (the insertion of an incorrect amino acid) can occur. The first is in the attachment of the amino acid to its cognate tRNA. This step has been shown to have errors in that similar amino acids can be attached to a tRNA (i.e., valine, leucine, and isoleucine). However, the slight degree of incorrect amino acid attachment is compensated by the editing domain of the aminoacyl-tRNA synthetase that quickly removes non-cognate amino acids from the tRNA. Thus, this is not a source of error under most circumstances. The other source of error is in the matching of the aminoacyl-tRNA to the correct codon in the A site on the ribosome. This error rate is about 3 errors in 10^4 polymerized amino acids. Thus, for a protein that is 50 000 in molecular weight, out of 20 copies made, 17 would be perfect and 3 would be mutant. These mistakes in many instances may not be biologically significant as the errors in reading the genetic code tend to replace one amino acid with a similar one (i.e., leucine with valine). In addition, while there are numerous proteins that have molecular weights above 500 000, in most instances these proteins are not a single polypeptide chain, but an aggregate of multiple subunits. In this way, high molecular weight complexes can be assembled with perfect subunits.

Global Regulation of Protein Synthesis

At a first glance, control of translation is quite complex and incompletely understood as there are a number of initiation factors that undergo co- and post-translational modification (for a total of 40 or more co- and post-translational modifications). Some of these may be small contributors (perhaps 5–10% increase or decrease in activity) or these modifications may influence the half life of the proteins and thus their total abundance. However, there are three well-established mechanisms for regulation that are affected by phosphorylation, two of which are inhibitory (eIF2 and eEF2) and one that is stimulatory (4E-BP). The regulation of eIF2 and 4E-BP activities stems directly from the 80S initiation pathway shown in Figure 2. The site of regulation is the recycling steps, steps 7, and 8. Generally, in eukaryotes, initiation is a predominant step at which regulation of protein synthesis is achieved.

There are 4 specific eIF2 kinases that phosphorylate serine 51 of the α subunit of eIF2, therefore inhibiting its activity and substantially downregulating cap-dependent initiation: GCN2 (activated by amino acid starvation); HRI (activated by low heme concentrations, mostly in erythrocytes), PKR (activated by double-stranded RNA) and PERK, an endoplasmic reticulum kinase located in the ER membrane (activated by oxidative stress or unfolded proteins) (Baird and Wek, 2012; Kimball and Jefferson, 2010). Although not well characterized, one or more of these kinases seems to also be activated by other stress signals as well. This phosphorylation yields an eIF2 that when it exits the initiation pathway as eIF2PO₄•GDP binds to eIF2B tightly, but does not exchange the bound GDP for GTP. As there is roughly 5 to 10 times as much eIF2 as eIF2B, when 20% of the eIF2 is phosphorylated, protein synthesis is almost 100% inhibited as there is no free eIF2B to catalyze the nucleotide exchange. This leads to a marked reduction in ternary complexes (eIF2•GTP•Met-tRNAi^{Met}) for initiation. As might be predicted from the initiation flow scheme in Figure 2, this reduction in protein expression tends to be non-mRNA specific (i.e., the translation of most mRNAs will be affected to the same degree), with the exception of those that might rely on the activity of initiation factor eIF2D (Dmitriev *et al.*, 2010), capable of mediating ribosomal recruitment of Met-tRNAi^{Met} in a GTP-independent manner, or which utilize initiation factor and Met-tRNAi^{Met}-independent pathways to initiate translation of their mRNAs, like cricket paralysis virus (CrPV) IRES. However, these cases are believed to be rather rare.

In a similar manner, when eIF4F exits the initiation pathway, it appears to do so as individual subunits that then need to be recombined to form active eIF4F (Merrick, 2010). During the time that eIF4E exists as a free subunit, it is susceptible to 4E-BP binding protein which sequesters the eIF4E and prevents the reformation of an active eIF4F molecule. The binding by 4E-BP is controlled by phosphorylation and is in the mTOR pathway where upregulated phosphorylation correlates with increased protein synthesis (Livingstone *et al.*, 2010; Huo *et al.*, 2011; Hinnebusch and Lorsch, 2012). In this case, phosphorylation of 4E-BP blocks its ability to compete with eIF4G for binding eIF4E and thus, active eIF4F is formed. This generally occurs under conditions favorable for growth. In contrast, when a stress occurs and there is down regulation of the mTOR pathway, 4E-BP becomes dephosphorylated and binds tightly to eIF4E reducing the pool of active eIF4F. As eIF4F is associated with mRNA activation (Figure 2, step 3), a reduction in eIF4F activity leads to a reduction in total protein expression. However, unlike eIF2, it tends to be mRNA specific in that inefficient mRNAs may have their level of expression reduced by 90% while efficiently translated mRNAs may only see a 10–20% reduction in expression; that is, the reduction of eIF4F activity drives competition between mRNAs for the limiting eIF4F available.

A secondary consequence of either regulation type is that some mRNAs are upregulated under these circumstances. mRNAs that contain an upstream ORF (uORF) are often upregulated under conditions of eIF2 phosphorylation while mRNAs that contain an internal ribosome entry site (IRES) are often upregulated under conditions where eIF4F activity is reduced (as there is reduced competition for initiation factors used in the normal cap-dependent translation). Both of these

types of responses are to trigger adaptation to the particular stress encountered.

The regulation of eEF2 activity is through the eEF2 kinase which is activated by calcium. This regulation makes sense given the release of calcium in the muscle during exercise. Under these circumstances, slowing the elongation rates reduces the energy drain of protein synthesis at a time when energy is needed for work (remembering that the incorporation of one amino acid into the growing polypeptide chain requires 4 high energy phosphates). Release of calcium under other circumstances is also consistent with energy saving (apoptosis and autophagy) under conditions of stress. This reduction in eEF2 activity slows the elongation rate of all proteins and thus reduces the expression from mRNAs in a roughly equivalent manner (as was seen with reduction of eIF2 activity and the level of ternary complexes). eEF2 is also a target of diphtheria toxin produced by *Corynebacterium diphtheriae*, that causes diphtheria. Diphtheria toxin catalyzes the transfer of NAD⁺ to a diphthamide (a modified histidine) residue in eEF2, thereby inactivating the protein. *Pseudomonas aeruginosa* exotoxin A and *Vibrio cholerae* cholera toxin also utilize a similar ADP-ribosylation mechanism to inactivate eEF2. These toxins are extremely potent and irreversibly inhibit the elongation step of protein synthesis.

mRNA Specific Regulation

The examples cited below are examples of mRNAs whose expression is regulated via a protein that binds to this specific mRNA (or a family of mRNAs) and affects its translational efficiency (through influencing initiation, elongation, or termination steps), half life or cellular localization. Due to space restrictions, we have mostly referenced these types of regulation to a series of books from Cold Spring Harbor Press that provide chapters to explore this regulation in further detail. The advantage of mRNA specific regulation, in contrast to just control of mRNA levels by regulating transcription, is the rapid change possible, often triggered by covalent modification.

Regulation of Protein Expression

5' UTR

RNA binding proteins, affects translational efficiency.

Cap-dependent translation (i.e., iron response element-binding protein) (Rouault and Harford, 2000).

IRES-mediated translation (i.e., IRES transacting acting factors or ITAFs) (Doudna and Sarnow, 2007; Elroy-Stein and Merrick, 2007; Komar and Hatzoglou, 2011).

3' UTR

RNA binding proteins affect mRNA half life (i.e., ARE or adenosine-uracil rich elements and ARE-BPs) (Darnell and Richter, 2012).

RNA binding proteins affect eIF4F/PABP interactions and translational efficiency (i.e., cytoplasmic polyadenylation element-binding protein or CPEB) (Thompson *et al.*, 2007; Gebauer *et al.*, 2012; Darnell and Richter, 2012) and block eIF4F(eIF4G)-eIF3 interaction and initiation (Jia *et al.*, 2013).

RNA binding proteins affect cellular localization of mRNA (i.e., Smaug and nanos mRNA) (Gavis *et al.*, 2007; Gebauer *et al.*, 2012; Lasko, 2012).

Glossary

Calnexin/calreticulin binding and release cycle It describes a cycle, in which nascent polypeptide of glycoproteins carrying the core oligosaccharide with one glucose residue ($\text{GlcNAc}_2\text{Man}_9\text{Glc}_1$) will bind to calnexin or calreticulin, but to be released when the glucose residue is removed. A reglucosylation of the oligosaccharide, occurring when the nascent polypeptide remains incompletely folded, will lead to the glycoprotein into another binding to and release from calnexin or calreticulin.

ER-associated degradation (ERAD) The process through which improperly folded substrate proteins in the endoplasmic reticulum (ER) lumen are selectively delivered back to the cytosol for eventual cleavage.

ER-related folding diseases Diseases caused by the defects of the folding and assembly of one particular protein or all secretory proteins in general in the ER, which will result in either the loss of function of a particular protein or formation of deposits of aggregated proteins in the ER lumen and thus cause ER malfunctioning, all to be harmful to the cells.

Molecular chaperone It is also called heat shock protein or stress protein. It initially interacts with its clients, being fully or partially unfolded nascent polypeptides or mature proteins, to prevent their aggregation but later release the clients, thus to facilitate their translocation, folding, assembly, or degradation.

Nascent polypeptides Polypeptides that are being synthesized but not yet folded/assembled into their native and functional structures in cells.

Oligosaccharyltransferase (OST) A multi-subunit ER membrane-associated protein complex that catalyzes the *en bloc* transferring of the core oligosaccharide of 14 monosaccharide residues ($\text{GlcNAc}_2\text{Man}_9\text{Glc}_3$), that is preformed and carried by the ER membrane-associated lipid dolichol, to the Asn residue of an Asn-X-Ser motif present in nascent polypeptides during its translation and translocation into the ER lumen.

Protein biogenesis The whole process to form functional proteins in living cells.

Protein disulfide isomerase (PDI) A protein that facilitates the formation of correct disulfide bonds in proteins by shuffling disulfide bonds, stabilizing proper intermediates, and resolving aberrant disulfide bonds via a thiol-disulfide exchange reaction, with the transient formation of mixed disulfide bond between PDI and its substrate proteins.

Retrotranslocon The ER membrane-embedded protein complex that facilitates the translocation of improperly folded substrate proteins in the ER lumen back into the cytosol for elimination. This complex has not yet been clearly characterized.

Sec61 translocon The multi-subunit protein complex that forms the conducting channel on the ER membrane, facilitating the translocation of nascent polypeptides of secretory proteins into the ER lumen.

Signal peptidase complex (SPC) The multi-subunit protease associated with the ER membrane, that specifically cleaves at C-terminal end of the signal peptides of nascent polypeptide chains.

Signal peptide A short N-terminal extension of sequences present in the nascent polypeptides of secretory proteins, that target them to the ER lumen (or certain other organelles) but be subsequently removed from the mature protein.

Signal recognition particle (SRP) A cytosolic ribonucleoprotein (containing both protein and RNA) complex that selectively delivers the ribosomes that are synthesizing secretory proteins to the ER membrane of eukaryotic cells (or the plasma membrane in prokaryotic cells).

SRP receptor The protein embedded on the ER membrane (or plasma membrane in prokaryotic cells) that interacts with the SRP that is bound to a ribosome which is synthesizing a secretory protein.

Unfolded protein response (UPR) The multiple ER to nucleus signaling transduction pathways that are switched on in responding to the accumulation of unfolded proteins in the ER lumen, resulting in the induction of a large number of proteins, whose function will strengthen the function of the ER and recover the homeostasis in ER.

For a protein to exhibit biological function, it has to be delivered to a proper cellular location after being synthesized on the cytosolic ribosomes. Proteins to be secreted to the extracellular milieu, like hormones, certain enzymes, and defense proteins (like IgG), are first translocated into the membrane-enclosed space, or lumen of the endoplasmic reticulum (ER) in all eukaryotic cells. There they are folded, assembled, and modified before being further transported to their final destination via the Golgi apparatus. Additionally, many

membrane proteins are also folded and assembled in the ER membrane for their production in cells (i.e., biogenesis), using many similar protein factors and mechanisms to be discussed here. Such a targeting or sorting process was found to be specified by intrinsic structural elements, commonly linked to the N-terminal of the precursor protein but will be removed from the mature protein. Cells that are specified to produce secretory proteins, like those of the pancreas (producing peptide hormones insulin and glucagon) and the mature B cells

(producing antibodies such as IgG) commonly possess a more extended ER system. It was the work of such scientists as George Palade and Gunter Blobel that unveiled the key role of ER in such protein biogenesis (to be explained in the Glossary) processes. For their remarkable contributions, Palade and Blobel were respectively awarded the Nobel prizes in Physiology or Medicine in 1974 and 1999 (Palade, 1975; Günter Blobel, 2000).

The ER membrane typically constitutes more than a half of the total membrane of an average animal cell, extending as a continuous enclosing of tubules and flattened sacs throughout the cytosol. The ER lumen is topologically equivalent to the outside of the cell with a composition significantly different from the cytosol, providing a unique versatile and robust compartment for the posttranslational maturation of secretory proteins. It meanwhile provides a stringent quality control checkpoint for the proteins matured there, such that only proteins, which successfully form their structures will be further transported, those otherwise will be retained and removed. As a matter of fact, most of the resident ER proteins are involved in one way or another for the biogenesis or quality control of the secretory or membrane proteins that are translocated across the ER.

Nascent Polypeptides Are Specifically Recognized and Delivered to the ER Membrane in a Co- or Posttranslational Manner

Delivery to the ER is an early and decisive step for nascent polypeptides to be exported to the extracellular space. Such an export process might be roughly divided into such key steps as recognition and delivery to the ER membrane, translocation across the membrane (or into it for the membrane proteins), formation of native structure (or folding and assembly), and departure from the ER for further transport to the final destination.

Although early biochemical and genetic studies demonstrated that nascent polypeptides are mostly transported across the ER membrane in a co-translational ('during translation') fashion, some, especially those of small size (as well as 'tail-anchored' membrane proteins, i.e. those anchored via a C-terminal tail), are believed to depend on a post-translational ('after translation') pathway. Both the co- and posttranslational translocations are considered to use the same protein translocation channel, or translocon, on the ER membrane, with the initial targeting stage differing from each other.

Nascent Polypeptides Possessing a Unique Signal Peptide Are Selectively Delivered to the ER Membrane

It has been a major scientific discovery of Blobel's laboratory that proteins rely on intrinsic structural signals, either as an extension at their N-terminal (for the secretory proteins) or as an internal sequence (for the membrane proteins), for their selective delivery to the ER. The N-terminal signal peptides of different secretory proteins commonly consist of 16–30 amino acid residues that share hardly any sequence similarity but only a tripartite organization as follows: a core of 6–12 hydrophobic residues flanked by one or more positively charged residues at its N-terminal side and polar uncharged residues at its C-terminal side (Milstein *et al.*, 1972; Blobel and Dobberstein, 1975; Martoglio and Dobberstein, 1998). It is this signal peptide that directs a nascent polypeptide to the ER membrane, with the help of a group of cytosolic factors that will be described in detail below (see Figure 1 and Table 1). Other than this rough feature of amino acid composition, much awaits to be learned about the signal peptide on how it exactly functions during the biogenesis of secretory proteins in the ER, for example, to retard the folding of the nascent polypeptides, to select and go through a particular co- or posttranslational translocation pathway.

Figure 1 Major events in delivering to and translocating across the ER membrane of nascent polypeptides for the secretory proteins. Both the co- or posttranslational translocation pathways are illustrated here. BiP, an isoform of the Hsp70 chaperone family present in the ER lumen; ER, endoplasmic reticulum; Hsc70, an isoform of the Hsp70 molecular chaperone family present in the cytoplasm; SP, signal peptidase; SRP, signal recognition particle. For further details, please refer to Table 1 and the text.

Table 1 Major complexes/factors involved in the translocation of secretory protein precursors into the endoplasmic reticulum of mammalian cells

<i>Name of complexes/factors</i>	<i>Known/proposed functions</i>
<i>Signal Recognition Particle (SRP)</i>	
SRP72	Forms heterodimers with SRP68; binds to the 7S RNA
SRP68	Forms heterodimers with SRP72; binds to the 7S RNA
SRP54	Binds to the signal peptide sequence of substrate proteins; interacts with the SRP receptor located on the ER membrane
SRP19	Binds to the S domain of the 7S RNA
SRP14	Forms heterodimers with SRP9; binds to the Alu domain of the 7S RNA
SRP9	Forms heterodimers with SRP14; binds to the Alu domain of the 7S RNA
7S RNA	A central regulator of SRP; mediating global reorganization of the SRP; coupling the GTPase cycle of SRP and SRP receptor to the cargo loading and unloading events of SRP
<i>SRP Receptor</i>	
SR α	A peripheral GTP-binding membrane protein associated with the integrated membrane protein SR β interacts with SRP54 to mediate SRP docking to the SRP receptor
SR β	A GTP-binding membrane-integrated protein that interacts with SR α and mediates docking to the Sec61 translocon
<i>Cytosolic Chaperones for Posttranslational Translocation</i>	
Hsc70	A cytosolic Hsp70 molecular chaperone that keeps the nascent polypeptide competent for posttranslational translocation
Hsp40	A co-chaperone of Hsc70 that functions in posttranslational translocation
TRC40	Delivers small secretory protein precursors to the Sec61 translocon for posttranslational translocation
Calmodulin	Delivers small secretory protein precursors to the Sec61 translocon for posttranslational translocation
<i>Sec61 Translocon</i>	
Sec61 α	Forming the major part of the protein-conducting channel on ER membrane
Sec61 β	A nonessential component of the Sec61 translocon
Sec61 γ	An essential component of the Sec61 translocon
<i>Auxiliary Translocation Factors</i>	
TRAM	The 'translocating-chain associated membrane' protein; interacts with weak signal peptide sequences, regulating membrane protein biogenesis
TRAP	The 'translocon-associated protein complex'; facilitate substrate specific translocation; assists membrane protein topogenesis
RAMP4	The 'ribosome associated membrane protein 4'; regulating protein glycosylation; stabilizing newly synthesized membrane proteins under ER stress; maintaining ER homeostasis and translocation efficiency
Sec62	Mediate posttranslational translocation of small secretory proteins; binding to the ribosome exit tunnel and Sec63; stabilizing the translocon
Sec63 (ERdj2)	A co-chaperone of BiP; mediates posttranslational translocation of small secretory proteins; regulate Sec62 recruitment to the Sec61 translocon

The signal recognition particle (SRP) helps deliver a nascent polypeptide to the ER for co-translational translocation

Co-translational translocation is viewed as the most common and effective mode for the delivery of nascent polypeptides to the ER. Its advantage is derived from the fact that the nascent polypeptide chains are not released into the cytosol; thus their potential aggregation and misfolding is intrinsically avoided. In animals, this pathway of translocation is known to depend on the cytosol-located SRP, a ribonucleoprotein complex containing six different protein subunits and a 300-nucleotide RNA molecule (Walter and Blobel, 1982; Gilmore *et al.*, 1982; Tajima *et al.*, 1986; Akopian *et al.*, 2013; for details, see Table 1). For the SRP, the SRP54 subunit is the most conserved across all species and is primarily responsible for binding to the signal peptide sequence of the nascent polypeptide. Interestingly, the SRP composition in prokaryotic cells was found to be much simpler (as a common phenomenon, many molecular processes are found to be much simpler in prokaryotes than in eukaryotes), only containing one single protein that is homologous to SRP54, thus termed Ffh

(abbreviated from 'fifty four homology') and a much shorter (only 110 nucleotides) RNA molecule.

The SRP is believed to recognize and bind to the ribosome-nascent polypeptide complex once its signal peptide sequence emerges from the exit of the ribosome (Figure 1). This SRP binding was found to temporarily halt the translation process until the nascent polypeptide is delivered to the translocation machinery on the ER membrane. SRP is thought to bring the bound ribosome-nascent polypeptide complex (its 'cargo') to the ER mainly by binding to the SRP receptor that is associated with the ER membrane and composed of two different subunits (for details, see Table 1). Uniquely, both the SRP and SRP receptor (a pair of molecular matchmakers) possess GTPase activities, which are only reciprocally activated upon their binding to each other, with the subsequent GTP hydrolysis apparently leading to certain conformation modulation that releases SRP from its receptor, allowing the SRP for a new round of cargo recruitment (Figure 1). This unique 'GTPase cycle' of the SRP and SRP receptor provides an exquisite spatial and temporal coordination in targeting the ribosome-nascent polypeptide complex to the ER membrane.

This dissociation of SRP and SRP receptor should occur to result in the transferring the ribosome–nascent polypeptide complex to the translocation machinery of the ER membrane, the mechanism of which is hardly known at this time. The RNA component in SRP plays a central regulatory role for the multiple and dynamic interactions involved in this delivery process.

Cytosolic molecular chaperone proteins may help deliver completely synthesized nascent polypeptides to the ER for posttranslational translocation

Despite the aforementioned advantages of the co-translational translocation pathway, it is becoming apparent that a significant portion of secretory proteins are targeted to the ER membrane using a SRP-independent posttranslational translocation pathway (Figure 1). This was initially observed to occur for the precursor of mating factor α in yeast cells (Hansen *et al.*, 1966). It was later found to occur for secretory protein whose size is too small (e.g., peptide hormones) for the ribosome to stably retain the nascent polypeptide, whose signal peptide is not of sufficient hydrophobicity for SRP recognition, or whose signal peptide is located at the C-terminal end (for the ‘tail-anchored membrane proteins’) and will emerge only after it is completely synthesized (Johnson *et al.*, 2013). For this, cytosolic ATP-dependent molecular chaperones such as Hsc70 are needed to transiently maintain the nascent polypeptide chain in a translocation-competent form (i.e., loosely folded or unfolded) and meanwhile to prevent their aggregation. In mammals, calmodulin was found to also play a role for bringing the nascent polypeptides to the ER for their posttranslational translocation. Meanwhile, the ER lumen-located BiP (also a molecular chaperone of the Hsp70 family) is believed to act as an ATP-dependent ‘molecular ratchet’ that minimizes the passive backward movement of the nascent polypeptide chain through the translocation channel, thus to ‘pull’ it into the ER lumen (Figure 1).

Conducting Channels Made of Integrated Membrane Proteins Translocate Nascent Polypeptides across the ER Membrane

The nascent polypeptides, recruited to the ER membrane either via the co- or posttranslational pathway, are subsequently translocated into the ER lumen by using basically the same protein-conducting channel, termed the Sec61 translocon in eukaryotic cells (or SecY complex in prokaryotic cells), that is facilitated by different auxiliary factors for different nascent polypeptides (see Table 1 and Figure 1).

The Sec61 Translocon Functions as the Protein-Conducting Channel on the ER Membrane

The Sec61 translocon on the ER membrane is a highly conserved multi-subunit protein complex that consists of three subunits, Sec61 α , Sec61 β , and Sec61 γ (of 476, 96, and 68 amino acid residues, respectively) in eukaryotic cells (Görlich and Rapoport, 1993; Osborne *et al.*, 2005; Table 1). The pore

of the channel is largely formed by the large Sec61 α subunit (or the homologous Sec Y subunit in prokaryotic cells). The Sec61 translocon is associated with many other protein factors, for example, the Sec62/Sec63 proteins that are needed for the posttranslational translocation (Table 1). Several additional proteins, such as the translocating-chain associated protein (TRAM), the translocon-associating protein (TRAP), and the ribosome associated membrane protein RAMP4, also apparently assist the translocon, but their detail functions are barely known (Table 1).

The driving force for co-translational translocation is apparently provided by the cytosol-located GTP-consuming ribosome that may push the nascent polypeptide through the Sec61 translocon, while that for posttranslational translocation is provided the ER lumen-located BiP. In addition, the translocon is presumed to open only when a signal peptide sequence of a transporting substrate becomes available, otherwise remain closed to maintain the barrier of the ER membrane lipid bilayer.

The Signal Peptide Is Cleaved at a Certain Time Point after the Nascent Polypeptide Chain Reaches the ER Lumen

The N-terminal signal peptide sequence of a nascent polypeptide chain is cleaved by a specific multi-subunit signal peptidase complex (SPC), that is associated with the ER membrane. The mammalian enzyme consists of five non-identical subunits (again only one single subunit in the bacteria), all being integrated in the ER membrane (Evans *et al.*, 1986; Dalbey *et al.*, 1997). The C-terminal region of the signal peptide contains crucial structural features required for this cleavage. Statistical analysis of the amino acid residues in the cleavage site led to the formulation of the (–1, –3) rule, by which the residues at the –1 and –3 positions (–1 is immediately before the cleavage site) are typically made up of small, neutral residues, such as Ala, Gly, Cys, and Ser, more often being the Ala-X-Ala motif.

The Nascent Polypeptides Form Their Native Structures in the ER Lumen with the Help of Multiple Factors

The secretory proteins fold and assemble in the ER, where for many proteins disulfide bonds are also formed and N-glycans (i.e., oligosaccharides linked to particular Asn residues) added. The ER is highly enriched in protein factors that promote efficient protein folding and ensure only correctly folded and assembled proteins be transported to their final destination. In this regard, improperly folded/assembled proteins are retained for further rounds of folding/assembly or eventual removal (Braakman and Bulleid, 2011; Fewell *et al.*, 2001; see Table 2, and Figure 2). Accordingly, proteins that have evolved to fold in the ER fail to fold correctly in the cytosol and vice versa. Undoubtedly, folding and assembly of secretory proteins is one of the main functions evolved for ER (in addition to lipid synthesis and calcium storage). Numerous chaperones and enzymes function, often redundantly, in the ER to ensure the formation of the correct native structures for a great diversity of secretory proteins.

Table 2 Major complexes/factors involved in the processing, folding, and quality control of secretory proteins in the lumen of the endoplasmic reticulum of mammalian cells

<i>Name of factors/complexes</i>	<i>Known/proposed functions</i>
<i>Modifying Enzymes</i>	
SPC	The 'signal peptidase complex' that specifically removes the signal peptide sequence in the ER lumen
OST	The 'oligosaccharyltransferase' that adds the core N-linked oligosaccharide to the substrate glycoproteins
Glucosidase I	Removes the outmost glucose residue from the core N-linked glycan
Glucosidase II	Removes the two inner glucose residues from the core N-linked glycan; releases glycoproteins from the lectin-like chaperones CNX/CRT
UGGT	The 'UDP-glucose:glycoprotein glucosyl transferase,' a protein folding sensor that re-glucosylates incompletely folded glycoproteins
α -mannosidase	Cleave a single mannose residue from the glucose-lacking N-linked glycan to extract glycoproteins from the CNX/CRT binding and release cycle
<i>Chaperones in ER Lumen</i>	
Calnexin (CNX)	An ER membrane associated lectin-like chaperone that binds to substrate glycoproteins via their monoglucosylated N-linked oligosaccharides, leading to their retention in ER
Calreticulin (CRT)	A soluble lectin-like chaperone of identical function as calnexin
BiP (GRP78)	A key molecular chaperone of the Hsp70 family in the ER lumen, function in translocation of nascent polypeptide into ER lumen, in unfolded protein response, in protein folding, in ERAD, in holding the IgG heavy chains before associating with IgG light chains during IgG formation in mature B cells
GRP94	A molecular chaperone of the Hsp90 family essential for secretion of specific clients and also for the removal of substrate proteins via the ERAD pathway
GRP170	Nucleotide exchange factor for BiP
Si1 (BAP)	Nucleotide exchange factor for BiP
ERdj1	BiP co-chaperone functioning in protein biosynthesis
ERdj3	BiP co-chaperone functioning in protein folding and ERAD
ERdj4	BiP co-chaperone functions in ERAD
ERdj5	BiP co-chaperone; a potential PDI involved in ERAD
ERdj6	BiP co-chaperone defending cells against ER stress
<i>Peptidyl Prolyl cis-trans Isomerases (PPlases)</i>	
Cyclophilin B	PPlase
FKBP7	PPlase; associates with BiP
FKBP9, 10	PPlase
FKBP11	Pancreas-specific PPlase
<i>Protein Disulfide Isomerases (PDIs)</i>	
PDI	Formation, isomerization, and reduction of disulfide bonds; potential chaperone; also function during ERAD pathway
ERp46	Protection against ER stress
ERp57	Calnexin/calreticulin-associated oxidoreductase
ERp72	Potential oxidoreductase
P5	Potential oxidoreductase; associates with BiP and forms mixed disulfide bonds with client proteins of BiP
ERp18	Potential oxidase
ERp29	Molecular chaperones preventing premature oligomerization, stimulating secretion
ERp44	Thiol-dependent ER retention; inositol 1,4,5-triphosphate receptor regulation
Ero1 α	Oxidase, regulation of redox conditions in ER; often work with PDIs
Ero β	Oxidase, induced by UPR, high expression in pancreas
<i>ERAD-Related Proteins</i>	
P97 complex	Associates with the ER membrane, function in ERAD to facilitate substrate retrotranslocation from ER lumen to cytosol
EDEM1-3	Lectin-like chaperones that are key ER factors for the recognition and targeting of glycosylated ERAD substrates
Os9	A lectin-like chaperone that delivers glycosylated ERAD substrates to the retrotranslocon
XTP3-B	A lectin-like chaperone that delivers glycosylated ERAD substrates to the retrotranslocon
HERP	Delivers non-glycosylated BiP substrates to the ERAD pathway
Derlin1-3	Candidates of retrotranslocation channel on the ER membrane
HRD1-SEL1L	Recruits misfolded ERAD substrates or other adapter proteins (e.g., Os9 and XTP3-B) to the E3 ligase complex on the ER membrane
P97-UFD-NPL4	A cytosolic complex for retrotranslocation of ERAD substrate proteins
<i>Unfolded Protein Response (UPR) Factors</i>	
Ire1 α	The 'inositol-requiring enzyme 1'; an ER transmembrane stress transducer, activated by forming homo-oligomers when unfolded protein accumulates in the ER lumen

(Continued)

Table 2 Continued

Name of factors/ complexes	Known/proposed functions
PERK	The 'protein kinase R-like endoplasmic reticulum kinase'; an ER transmembrane kinase serving as stress transducer, activated by forming homo-oligomers when unfolded protein accumulates in ER lumen
ATF6	The 'activating transcription factor 6'; an ER transmembrane transcription factor precursor that will exist as homo-oligomers under nonstress conditions, but dissociate into monomers that will be transported to the Golgi apparatus for cleavage and activation in response to unfolded protein accumulation in the ER lumen
XBP-1	A transcription activator produced upon Ire1 α activation
ATF4	A transcription factor activated in response to PERK activation
S1P and S2P	Golgi-resident proteases that will cleave ATF6 monomer precursor to release the activated ATF6 transcription factor in the cytosol

Protein Folding and Assembly in ER Occur as an Interplay between a Polypeptide's Primary Structural Information and a Variety of Folding Factors

The ER lumen provides an optimal and specialized milieu for the maturation of the itinerant nascent polypeptides. This is made possible by the presence of a large number of molecular chaperones and enzymes. This network of folding factors work collaboratively to minimize protein aggregation, facilitate native structure formation, ensure oligomeric assembly and monitor the quality of the products to be exported. These folding factors in the ER lumen might be divided into chaperones/co-chaperones, peptidyl prolyl *cis/trans* isomerases (PPIases), protein disulfide isomerases (PDIs) and glycan-binding proteins (such as calnexin and calreticulin discussed above). Many of these factors seem to play multiple or redundant functions. For example, the molecular chaperone BiP functions in the translocation, folding, assembly, and degradation of the substrate proteins (to be discussed below; Figure 2) and many proteins function as PDIs or PPIases (Table 2).

Similar to the molecular chaperones functioning in the cytosol, the ER-resident molecular chaperones such as BiP, GRP94 (an Hsp90), GRP170 (a nucleotide exchange factor of BiP), ERdj1-6 (Hsp40 family co-chaperones of BiP) usually function to shield the hydrophobic sequences of the nascent polypeptides and thus prevent their aggregation. In addition, most other folding factors present in the ER, for example, the PPIases and PDIs seem to also exhibit chaperone activities.

Secretory Proteins Form Their Disulfide Bonds in the ER Lumen

The disulfide bonds, often present in secretory proteins and virtually absent in cytosolic proteins, are formed in the ER lumen where a relatively high oxidative redox potential is commonly maintained and PDIs are abundant (Braakman and Bulleid, 2011). The PDI was initially discovered by Christian Anfinsen as an ER enzyme that facilitates the formation of correct disulfide bonds in proteins. This occurs as a protein-based relay of oxidation/reduction reactions, involving, for example, a PDI and the oxidoreductases Ero1 (associated with the ER membrane). The PDIs function to shuffle disulfide bonds, stabilize proper intermediates, and resolve aberrant

disulfide bonds via a thiol-disulfide exchange reaction, with the transient formation of mixed disulfide bond between PDI and its substrate protein (Figure 2). A remarkable number of PDI isoforms exists in the ER lumen (Table 2), implicating either a redundancy or specification in their functions.

Glycan-Recognizing Molecular Chaperones Facilitate the Folding of Glycoproteins in the ER Lumen

A majority of the secreted proteins are glycoproteins. As an early and common modification, the core oligosaccharide of 14 monosaccharide residues (GlcNAc₂Man₉Glc₃, in which GlcNAc is N-acetylglucosamine, Man is mannose and Glc is glucose) is preformed and carried by the ER membrane-associated lipid dolichol. It is then co-translationally transferred *en bloc* to an Asn-sequon (i.e., the Asn-X-Ser/Thr sequence) present in nascent polypeptides by the multi-subunit oligosaccharyltransferase (OST) in ER lumen near the translocon (Figure 2). Such a common glycan molecule seems to act as a key marker to reflect the folding status of the proteins it linked and their binding to the lectin-like chaperones, calnexin, or calreticulin.

Subsequent glucose trimming and reglucosylation will lead the glycoproteins into a calnexin/calreticulin binding and release cycle to promote their folding (Hammond *et al.*, 1994; Helenius and Aebi, 2004; Figure 2). For this, the consecutive trimming of two glucose residues by glucosidases I and II generates GlcNAc₂Man₉Glc₁, which becomes a high affinity ligand for the two lectin-like chaperones, the membrane-associated calnexin and the soluble calreticulin. This binding allows calnexin/calreticulin to bind/retain the glycoprotein substrates in the ER lumen and facilitates a new round of folding, which meanwhile prevents their aggregation and degradation. It has been demonstrated that calnexin/calreticulin also recruits the PDI ERp57 for promoting disulfide bond formation in the glycoproteins (Figure 2).

According to current understanding, the oligosaccharide becomes no longer recognizable by calnexin/calreticulin if the last glucose residue is removed from the oligosaccharide. It is presumed that glycoproteins released from these chaperones will exit the ER if correctly folded, but will be recognized and re-glucosylated by the folding sensor UDP-glucose: glycoprotein glucosyltransferase (UGGT) if remain unfolded, thus entering another round of calnexin/calreticulin binding

Figure 2 Major events for the folding and quality control of secretory proteins in the ER lumen. Illustrated here are the following: the calnexin/calreticulin (Cxn/Crt) binding and release cycle for the glycoproteins, the master regulatory roles of the Hsp70 member molecular chaperone Bip, the ER-associated degradation (ERAD) pathway, and the three signaling pathways for the unfolded protein response (UPR). Atf, activating transcription factor; Bip, an isoform of the Hsp70 molecular chaperone family; Crt, Calreticulin; Cxn, calnexin; EDEM, ER degradation-enhancing-mannosidase like protein; eIF, eukaryotic initiation factor; ERp57, a protein disulfide isomerase; Ire1, inositol-requiring enzyme 1; OST, oligosaccharyl transferase; PDI, protein disulfide isomerase; Perk, protein kinase R-like endoplasmic reticulum kinase; UGGT, UDP-glucose:glycoprotein glucosyl transferase; Xbp-1, X-box binding protein 1, a transcription factor. For further details, please refer to [Table 2](#) and the text.

(Figure 2). Certain unfolded forms of the glycoproteins, either due to an overtime existence or an extensive structure distortion, may eventually get its mannose residues trimmed and thus become recognizable by other ER lectin-like chaperones that deliver them for degradation (see Figure 2 and below). How exactly these different fates of the glycoproteins (and nonglycoproteins) are determined in the ER lumen is still unclear. For glycoproteins, folding, trafficking, and degradation apparently rely on a common machinery and are thus highly integrated.

The Folding Factors in the ER Lumen Work as a Network or to Form Complexes in Folding Each Unique Client Protein

Studies indicate that the different folding factors, including the chaperones, PDIs and PPIases, do not work alone, but as a dynamic network for the maturation of each unique substrate proteins. For example, the BiP works sequentially with Hsp40 family co-chaperones, nucleotide exchange factors, as well as the Hsp90 protein (GRP94) in fulfilling its multiple functions for the translocation, folding and assembly of nascent polypeptides, removal of misfolded proteins, and transduction of ER stress signals to the nucleus. On the other hand, chaperones such as BiP, GRP94, calreticulin, ERp72, and cyclophilin have been found to form complexes with such large secretory proteins as immunoglobulins, apolipoprotein B-100, and thyroglobulin. Apparently, they come together to meet the 'needs' of individual substrate proteins, as well as on the stage of folding that is being promoted.

The Folding and Assembly of IgG in the ER Lumen of the B Cell Involves Many Different Types of Folding Factors

The IgG molecule is a large and complex secretory protein that is assembled from two light and two heavy chains of multiple Ig (Immunoglobulin) domains, forming multiple intra- and interchain disulfide bonds. The biogenesis of IgG in effector B cells would conceivably depend on the functioning of many of the folding factors we discuss here (Haas and Wabl, 1984; Feige *et al.*, 2009, 2010). As a matter of fact, the key ER lumen molecular chaperone BiP was originally discovered as an 'Immunoglobulin heavy chain binding protein' (thus the name BiP) and was identified by virtue of its association with the unassembled IgG heavy chains, preventing the premature escape or aggregation of the incompletely assembled IgG molecules (Haas and Wabl, 1984).

Although a detail pathway remains to be defined, the folding and assembly of IgG apparently are considered to involve the following major events (Feige *et al.*, 2009, 2010). Folding of the individual Ig domains and formation of intra-chain disulfide bonds seem to begin during their co-translational translocation. BiP transiently interact with most of the domains during their folding. All constant domains except C_H1 ('constant domain 1 in the heavy chain') and most of the variable domains seem to fold autonomously but need PPIases to promote the rate-limiting correct formation of certain peptidyl prolyl *cis-trans* isoforms on the way to their final native state. The dimerization of two heavy chains is induced by their folded C_H3 structures, which will be further fixed by

the formation of interchain disulfide bonds between the hinge regions of the heavy and light chains. Interestingly, the C_H1 domain seems to remain unfolded, with its disulfide bonds unformed and thus stably bound to BiP until it interacts with the C_L domain ('constant domain of the light chain') that simultaneously displaces BiP. In other words, the folding of the C_H1 domain will be initiated upon its binding to the C_L. This includes the formation of the correct isoforms of a prolyl peptide bond in the C_H1 domain as promoted by a PPIase. A disulfide bond will then be formed between the interacting C_H1 and C_L domains, rendering the IgG molecules ready for secretion into the extracellular space. Chaperones, PDIs, and PPIases contribute to these multiple individual folding/assembly steps in IgG biogenesis in a cooperative manner.

A Comprehensive Quality Control System in the ER Lumen Ensures that Only Correctly Folded/Assembled Proteins Are Transported with the Misfolded/Misassembled Ones to be Degraded

Protein folding and assembly occur through non-covalent weak interactions and are thus inherently error prone. Folding factors have evolved not only to facilitate protein folding and assembly, but also to ensure a high standard of quality control, such that only correctly formed products be delivered to their final destination and those failed to reach the standard to be retained for another round of folding/assembly attempts or eventual removal (Braakman and Bulleid, 2011; Fewell *et al.*, 2001; Figure 2). As molecular sensors, the protein folding factors often play dual roles of both assisting the folding process and dispatching improperly folded proteins for destruction. As a result of such 'proof-reading,' the number of accumulated errors in the secreted proteins that the cells ultimately deploy is extremely low. Prolonged retention of misfolded and incompletely folded proteins in the ER actuates a dual stress response, which will help to remove the improperly folded proteins through degradation (see below) on the one hand, and to induce a comprehensive adaptive unfolded protein response (UPR) to increase the level of the quality control proteins (Figure 2).

Improperly Folded Proteins Are Disposed Through the ER-Associated Degradation (ERAD) Pathway

In spite of efforts to identify active proteases in the ER, none have been found, except the rather specific signal peptidase. Strikingly, the improperly folded proteins in the ER lumen were recently found to be degraded in the cytosol through a process termed ER-associated degradation (ERAD in short). For ERAD to occur, the unfolded and unassembled substrate proteins in the ER lumen are actually retrograded back to the cytosol, where they are ubiquitinated and degraded via the proteasome system (Werner *et al.*, 1996; Hiller *et al.*, 1996; Vembar and Brodsky, 2008). The ER membrane protein responsible for the retrotranslocation of substrate proteins from ER to cytosol has been intensively searched, but still with no clear consensus, with candidates include the Sec61 translocon itself and the Derlin proteins (Table 2).

According to the current understanding, the ERAD pathway occurs as follows (Figure 2). The misfolded substrate proteins in the ER lumen are first recognized by BiP for non-glycosylated proteins, by calnexin or calreticulin for glycosylated proteins, or by PDI for disulfide bond-containing proteins. The substrates are then targeted to the retrotranslocation machinery termed the 'retrotranslocon', through which the unfolded substrates are delivered back into the cytosol, the driving energy may derive from the ATP hydrolysis by the P97 protein complex (an AAA + ATPase). Upon exiting the retrotranslocon, the polypeptide chain is polyubiquitinated by an E₃ ubiquitin ligase, after which, further retrotranslocation is aided by the cytosolic ubiquitin-binding proteins. Once a polyubiquitinated substrate is displaced into the cytosol, it is then degraded by the 26S proteasomes.

Extensive trimming of the N-glycans in a misfolded glycoprotein leads to an increased exposure of hydrophobicity, marking it for ERAD. For this, when the three glucose and two mannose residues are trimmed from the N-glycan, the Man₇-GlcNAc₂ oligosaccharide-carrying glycoprotein becomes more likely to be recognized by such lectins as EDEM1 ('ER degradation-enhancing α -mannosidase like protein 1') or OS9 (Table 2), which then guides the misfolded substrate proteins to an E₃ ligase complex and thus the ERAD pathway (Figure 2). Molecular cues that direct different folding sensors to various nonnative substrate proteins remain largely unknown. One model suggests that the efficiency of productive folding and trafficking is not defined by a single feature, but rather by the combination of multiple ones, including, for example, protein stability and folding rate.

UPR Prepares the Cells to Recover from an ER Stress

When the ER is burdened with unfolded proteins, a comprehensive so-called UPR will be initiated to reestablish homeostasis through a sophisticated transcriptionally and translationally regulated signaling network (Kozutsumi *et al.*, 1988; Cox *et al.*, 1993; Haze *et al.*, 1999; Harding *et al.*, 1999; Moore and Hollien, 2012; Figure 2). This will result in a general remodeling of the whole secretory pathway, such that the capacity of the ER increases and the ER may even become enlarged to accommodate the increased requirements for its function.

The UPR is known to occur via three different ER to nucleus signaling pathways in mammalian cells (Figure 2). In each pathway, a different ER membrane-integrated protein functions as the stress sensor and transducer, which are respectively found to be the Ire1, the Perk, and the Atf6 (Table 2). The BiP protein again seems to play a key role by binding to and inhibiting them in the ER lumen under nonstress conditions, but dissociating from them under stress conditions. The dissociation of BiP will result in the homo-oligomerization of Ire1, which will lead to the autophosphorylation and activation of the ribonuclease domain of Ire1, promoting the synthesis of the transcription factor XBP-1 (Cox *et al.*, 1993; Moore and Hollien, 2012). Similarly, the dissociation of BiP will result in homo-oligomerization of Perk, which will attenuate cell protein translation in general, but conversely enhances translation of Atf4 (analogous to the heat shock response), another transcription factor (Haze *et al.*, 1999; Moore and Hollien, 2012). In contrast to Ire1 and Perk, the dissociation of BiP results in the

disassembly of the Atf6 homo-oligomer into monomers, which will then be translocated to the Golgi apparatus where it is cleaved by the protease S1P ('site-1 protease') or S2P (Harding *et al.*, 1999; Moore and Hollien, 2012). The cytosolic domain cleaved from Atf6 also functions as a transcription factor. The three transcription factors that are activated through the three signaling pathways, XBP-1, Atf4, and Atf6, will subsequently induce the expression of a large number of proteins that are involved in such processes as protein biogenesis, protein quality control, and ERAD in ER. Together, these transcriptional regulations, in combination with the additional Ire1-mediated decay of mRNAs associated with the ER membrane and Perk-mediated general translational suppression, are believed to restore and strengthen ER function under stress conditions. The UPR signaling pathways will be attenuated and turned off upon the alleviation of the ER stress condition, apparently through the action of a few negative feedback loops. Although the general output of the UPR is to restore ER homeostasis, sustained and unresolved ER stress may induce apoptosis through the intrinsic mitochondrial apoptosis pathway.

The BiP Chaperone Is a Central Player for Protein Biogenesis and Quality Control in the ER

BiP was initially identified as a glucose-regulated protein named as Grp78 and independently as an immunoglobulin heavy chain binding protein (Haas and Wabl, 1984; Munro and Pelham, 1986). It was then demonstrated to be an ER-located member of the ATP-dependent Hsp70 family of molecular chaperones and play a central role for the protein biogenesis and quality control in the ER (Dudek *et al.*, 2009).

The major roles of BiP in ER may be summarized as follows (Figure 2). First, it facilitates the translocation of nascent polypeptides into the ER lumen by acting as a molecular ratchet (see above). For this, BiP is apparently recruited to the translocon by binding to its co-chaperone Sec63, a member of the Hsp40 family. This transient binding of BiP meanwhile will inhibit the intra- or intermolecular interaction of the nascent polypeptides to facilitate their subsequent maturation in the ER lumen. Second, BiP is also known to facilitate the disposal of those more permanently misfolded and unassembled proteins. For this, BiP directs the substrate proteins to the ER-associated degradation pathway. How BiP distinguishes the incompletely folded and the permanently misfolded polypeptides is an issue remains unresolved. One proposal is that the ER is divided into different sub-domains in which folding and degradation occur in a compartmentalized manner, thus each could be worked upon by a distinct set of chaperones and co-chaperones. For example, in yeast, the BiP co-chaperones ERdj3 or ERdj6 apparently mediates folding, while ERdj4 or ERdj5 mediates degradation (Table 2). Thirdly, BiP is also known to play key modulatory roles in the three signal transduction pathways between the ER lumen and the nucleus for the UPR (Figure 2).

The Malfunctioning of Protein Folding in ER Are Known to Cause Folding Diseases

The ER is a key cellular site for the biogenesis of many secretory (and membrane proteins). Failed folding, transport, and

degradation in ER have been found to be the basis of many human diseases termed ER-related folding diseases (Aridora and Hannan, 2000; Hebert and Molinari, 2007). These diseases can be roughly categorized into three groups. The first group is due to the retention and subsequent degradation of mutated cargo protein molecules that fail to be exported by the ER machinery. One disease for this is the chronic lung defect called emphysema, which is caused by a mutation leading to the replacement of Glu342 by a Lys residue in the α 1-antitrypsin, a glycoprotein inhibitor of the elastase (a serine protease) in the lung. This mutant protein is retained in the ER of hepatocytes, a major site of α 1-antitrypsin production and secretion, and is subsequently degraded. This lack of inhibition of elastase leads to the degradation of the elastin protein in the lungs, causing emphysema. The second group is due to the accumulation of substrate proteins that are retained but inefficiently degraded in the ER. This will initiate the ER UPR, the signaling that may culminate in apoptosis of the host cell. The Glu324 to Lys mutant protein of the α 1-antitrypsin described above was also found to accumulate in the liver cells, forming intracellular deposits that damage the liver cells and cause such liver disease as cirrhosis. The third group is due to defects in the ER transport machinery or the UPR signaling.

A great number of human diseases have been related to the biogenesis defects of different secretory (and membrane proteins) in the ER, the detail understanding of the molecular mechanism of these diseases will certainly allow us to find ways to prevent or treat these diseases.

The Protein Biosynthetic Machinery of Mitochondria

LL Spemulli, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

© 2016 Elsevier Inc. All rights reserved.

General Background

Mitochondria are subcellular organelles found in eukaryotic organisms that function as the powerhouses of the cell. They produce about 90% of the energy used by higher cells as well as carrying out additional metabolic and cellular functions. Mitochondria are thought to have developed from endosymbiotic bacteria. These bacteria are thought to have been engulfed by other cells during the evolution of eukaryotes. They transferred much of their original genetic information to the nucleus leaving a small amount in the residual structures, mitochondria. These organelles retain a small amount of DNA and carry out transcription and translation for the expression of the limited number of genes remaining within the organelle.

Information Content of Mitochondrial DNA

The mitochondrial DNA from about 3000 organisms has been sequenced. In most mammals, mitochondrial DNA is a very compact double-stranded DNA about 16 000 base pairs in length. This DNA generally codes for 2 ribosomal RNAs (rRNAs), 22 transfer RNAs (tRNAs) and 13 polypeptides. The proteins encoded are all membrane embedded subunits of the respiratory chain complexes including 7 subunits of Complex I (NADH-ubiquinone oxidoreductase), one subunit of Complex III (ubiquinone-cytochrome c oxidoreductase); three subunits of complex IV (cytochrome oxidase) and two subunits of complex V (the ATP synthase).

Plant mitochondrial genomes are much larger than those found in metazoans ranging from 200 to 2400 kilobase pairs (kbp). In some cases there is a large master circle and other various sized DNAs that appear to be derived from it (Scheffler, 2008). The arrangement of the genes is quite variable but the information content is limited. For example, the *Arabidopsis* mitochondrial genome is just under 370 000 base pairs and consists of three different configurations of circular molecules. It encodes 3 rRNAs, 22 tRNAs, the standard proteins of the respiratory chain complexes with an extra subunit of complex V included. Plant mitochondrial genomes often encode a few ribosomal proteins. There are introns in certain genes and RNA editing must occur.

Fungal mitochondrial genomes also show significant variability although most are between 40 and 60 kbp. The best studied of these is from the yeast *Saccharomyces cerevisiae* which is 85 kbp and encodes 2 rRNAs, 24 tRNAs, 7 proteins of the respiratory chain and ATP synthase as well as a ribosomal protein. Yeast mitochondrial genes often contain introns and certain yeast strains encode additional proteins involved in the removal of these introns.

Components of the Translational System

Mitochondrial Messenger RNAs

Mitochondrial DNA is transcribed to create messenger RNAs (mRNAs) used by the organellar translational apparatus (Figure 1). In humans and other mammals, both strands of the DNA are transcribed into long polycistronic RNAs, transcripts carrying the coding information for multiple products. These transcripts are processed into 9 monocistronic and 2 dicistronic mRNAs before translation. The polycistronic transcripts also include the coding information for the rRNAs and tRNAs. In many cases, the tRNAs appear to serve as 'punctuation marks' specifying where endonucleases should cut the primary transcript to release the appropriate RNAs (Ojala *et al.*, 1981). In mammals, the mitochondrial mRNAs are quite unusual. They have an almost complete lack of 5' and 3' untranslated nucleotides. In humans the translational start codon is directly at the 5' end in 8 of the eleven 5' reading frames. It is located within 3 nucleotides of the 5' end of the other three mRNAs (Anderson *et al.*, 1982; Montoya *et al.*, 1981). The unusual structure of these mRNAs argues that the mechanism used by mitochondrial ribosomes to recognize the translational start site differs significantly from the mechanisms found in bacteria and the eukaryotic cytoplasm. In prokaryotes, the 16S rRNA contains a polypyrimidine tract near the 3' end which plays an important role in initiation complex formation by hydrogen bonding to a polypurine sequence (called the Shine/Dalgarno sequence) in the mRNA. In contrast, eukaryotic cytoplasmic mRNAs have a 5' cap structure which facilitates the binding of the 40S subunit to the mRNA. The 40S subunit then migrates in a 5' to 3' direction and usually initiates at the first AUG codon (Merrick, 1992; Kozak, 1992). Since mitochondrial mRNAs are not capped (Wolstenholme, 1992) and lack a Shine/Dalgarno sequence, neither the prokaryotic nor cytoplasmic mechanism for translational initiation can occur in this system. Mammalian mitochondrial mRNAs also generally lack significant 3' untranslated regions (UTRs) and, in many cases, the termination codon is completed by the polyadenylation of the 3' end of the mRNAs (Hirsch and Penman, 1974). The poly(A) tail at the 3' end of the mRNA is generally 40–60 residues in length and is believed to increase the stability of the mRNA.

In contrast to the mRNAs in mammals, plant mitochondrial mRNAs often have extensive 5' and 3' UTRs. They undergo extensive processing including the generation of multiple 5' ends. RNA editing (C to U) is observed and both cis- and trans-splicing is used for the removal of introns in the protein coding genes (Scheffler, 2008). The 3' ends of these mRNAs may be polyadenylated; however, unlike the situation in mammals, polyadenylation appears to serve as a signal for the degradation of the mRNA rather than serving to stabilize them (Chang and Tong, 2012).

Figure 1 Comparison of mRNAs from mitochondria with those from bacteria and the eukaryotic cell cytoplasm: the black lines indicate untranslated regions. The lengths of these lines correspond roughly to the sizes of the 5' and 3' untranslated regions. The red boxes are open reading frames (ORFs) encoding proteins. The sizes on the ORFs vary considerably. S/D indicates the presence of a Shine/Dalgarno sequence. Codons used for initiation (AUG or AUA) are shown. The small circle on the eukaryotic mRNA represents the 5' cap structure. The X indicates that polyadenylation signals destabilization of the mRNA.

In *S. cerevisiae*, the processed mRNAs are monocistronic and have 5' UTR sequences that play a role in translational initiation as described below. In *S. cerevisiae* the mitochondrial mRNAs are not polyadenylated (Chang and Tong, 2012).

A particularly interesting situation is observed with the kinetoplast mRNAs observed in the trypanosomatid protozoa including *Leishmania major* and *Trypanosoma brucei*. The kinetoplast is a network of circular DNA molecules contained within a large mitochondrion located near the base of the flagellum. In these organisms, initial polycistronic mitochondrial precursor RNAs are endonucleolytically processed. Many of the pre-mRNAs produced are extensively edited through a process that inserts and deletes uridines at the direction of small guide RNAs. Mature mRNAs in the kinetoplast have long poly(A/U) tails of 200–300 residues that stabilize them and make them competent for translation (Aphasizhev and Aphasizheva, 2013).

Mitochondrial tRNAs

Genetic code in mitochondria

Mitochondrial genomes of many organisms use a variation of the universal genetic code. Further, there is clearly not a universal mitochondrial genetic code and codon assignments vary in different lineages (Watanabe, 2010). One of the most interesting changes is the use of the Ile codon AUA for Met in most metazoans, making AUA an important initiation codon. Further, all animals have reassigned the 'universal' termination codon UGA as a Trp codon. In some cases, novel post-transcriptional modifications of mitochondrial tRNAs have developed to facilitate reading the altered code. Unlike the mitochondria of many organisms, the mitochondria of green plants use the universal code.

Import of tRNAs

Mammalian mitochondria, with the exception of certain marsupials, encode all 22 tRNAs that are required for the translation of the modified genetic code used in this organelle. Of particular note is that animal mitochondrial DNA encodes a single gene for tRNA^{Met} that functions in both initiation and elongation. Normally, protein biosynthetic systems have two tRNA^{Met} species, one used for initiation and the other for chain elongation (Schneider, 2011).

In contrast to animal systems, plant mitochondria often import a number of their tRNA species. However, the number and the amino acid specificity of the imported tRNAs varies widely from one plant system to another even among closely related species. The underlying biological basis for the differences observed is not clear, but suggests that the evolution of the import systems undergoes rapid evolutionary change (Schneider, 2011).

Although *S. cerevisiae* mitochondrial DNA has tRNA genes for all 20 amino acids, this organism imports a tRNA^{Lys} and possibly two tRNA^{Gln} species from the cytosol (Duchene et al., 2009). The mitochondrial genomes of trypanosomatids do not contain tRNA genes and these organisms import all of their tRNAs from the cytosol (Tan et al., 2002).

Structural features of mitochondrial tRNAs

Animal mitochondrial tRNAs have a number of unusual features distinguishing them from the tRNAs found in other systems. They are shorter and structurally weaker than their prokaryotic or eukaryotic cytoplasmic counterparts. Many of these tRNAs can be folded into an L-shaped tertiary structure, but the D-loop/T-loop interactions in the elbow region do not exist or are considerably different from those of canonical tRNAs. Mitochondrial tRNAs have been classified into five

Figure 2 Classes of tRNAs found in animal mitochondria. Type 0 is considered the classical cloverleaf structure with acceptor stem, D-arm, T-arm and anticodon stem/loop found in the tRNAs for prokaryotes and the eukaryotic cell cytoplasm. Many mitochondrial systems have tRNAs that deviate from this classical structure as indicated in types I-IV.

groups on the basis of their structural characteristics as summarized in [Figure 2](#) ([Watanabe, 2010](#)).

In contrast to observations in animals, mitochondrial tRNAs in higher plants have retained the canonical tRNA structure observed in prokaryotes and the eukaryotic cytosol. Since many plant species import a number of cytosolic tRNAs for use in the mitochondrion, this conservation of structure is expected. Fungal and trypanosomatid mitochondrial tRNAs also generally fold into the classical structure.

Aminoacylation of mitochondrial tRNAs

The genes for 38 aminoacyl-tRNA synthetases (aaRS) have been annotated in the human genome. Of these, 17 encode mitochondrial aaRS distinct from the corresponding cytosolic enzymes. Two genes encode both mitochondrial and cytosolic forms. There is no apparent gene for GlnRS and Gln-tRNA^{Gln} is thought to be generated through transamidation of Glu-tRNA^{Gln}.

In the *S. cerevisiae* genome, the genes for 35 aaRS have been convincingly annotated. In this organism, two genes are found for 15 aaRS; one of these encodes the cytosolic form of the enzyme and the other codes for the mitochondrial form. Five aaRS are shared between the two compartments. In *T. brucei* and *L. major*, the same aaRS is used in both the cytosol and mitochondria. This idea is compatible with the import of cytosolic tRNA for use in the kinetoplast ([Duchene et al., 2009](#)).

The situation in plants can be more complex since there is an additional translational system in the chloroplast. No aaRS are encoded in the mitochondrial or chloroplast DNA. Specifics vary in different plant species but, in general, the aaRS can be divided into several classes: (1) enzymes used only in the cytosol, (2) aaRS imported into both mitochondria and chloroplasts, (3) enzymes that function both in the cytosol and mitochondria, (4) enzymes that are localized only in chloroplasts. In general, there do not appear to be enzymes that are targeted solely to mitochondria.

Mitochondrial tRNA and aaRS in human disease

Genetic diseases leading to mitochondrial malfunction are classified into two groups: (1) mutations in nuclear genes encoding mitochondrial proteins and (2) mutations in mitochondrial DNA. This latter class is characterized by maternal inheritance. Diseases arising from mitochondrial dysfunction display a wide variety of clinical symptoms generally involving tissues that have high energy requirements including skeletal and cardiac muscle, neurological tissues and the renal and endocrine systems ([Kononova and Tynismaa, 2013](#); [Rotig, 2011](#)). When a mutation arises in mitochondrial DNA, it coexists with wild-type DNA since there are many copies of the mitochondrial genome in each organelle and cell. When the mutated DNA exceeds a threshold level, clinical symptoms appear.

While the genes for tRNAs constitute only about 10% of the human mitochondrial genome, mutations in these genes

account for about 50% of the diseases arising from mutations in mitochondrial DNA (Suzuki *et al.*, 2011). One of the most common defects in mitochondrial protein synthesis and respiratory chain activity is caused by a tRNA^{Leu} mutation associated with mitochondrial myopathy, encephalopathy, lactic acid acidosis, and stroke like episodes (MELAS). Approximately 80% of MELAS patients have an A to G mutation at position 3243 (A3243G) in the mitochondrial tRNA^{Leu} gene. This mutation leads in part to defective processing, reduced aminoacylation and an abnormal tertiary structure. Perhaps the most serious defect is that the cell cannot create the modified nucleotide, 5-taurinomethyluridine (tm5U), in the 5'-position of the anticodon of the affected tRNA. As a result, the translation of the Leu codons is deficient leading to a reduction in the synthesis of the mitochondrially encoded subunits of the respiratory chain complexes.

All of the mitochondrial aaRS are encoded in the nuclear genome. Mutations in nine of these have been associated with human genetic diseases. The clinical symptoms differ from one synthetase to another but the most common clinical symptom is encephalopathy (Kononova and Tynismaa, 2013). Only mutations that allow a certain level of residual aminoacylation have been observed since a full loss of function would be lethal.

Mitochondrial Ribosomes

As a group mitochondrial ribosomes present a diverse set of particles that differ from both prokaryotic and eukaryotic cytosolic ribosomes in their specific properties (Table 1). The most detailed structural studies to date have been carried out on bovine mitochondrial ribosomes and on kinetoplast ribosomes.

Mammalian mitochondrial ribosomes have sedimentation coefficients of about 55S and consist of a 28S small subunit (SSU) and a 39S large subunit (LSU) (O'Brien, 1971). Only two rRNA species, 12S in the SSU and 16S in the LSU, are observed. These ribosomes are only 25–30% RNA compared to bacterial ribosomes which are 60–70% RNA and eukaryotic cytoplasmic ribosomes which are 50–60% RNA (van Holde and Hill, 1974). The rRNAs show little primary sequence identity to other rRNAs. They fold into a secondary structure that has overall similarity to that of cytoplasmic rRNAs but show a complete erosion of certain features of the secondary structure.

The bulk of the mass of the mammalian mitochondrial ribosome consists of proteins (Koc *et al.*, 2010, 2013). These proteins fall into two classes – those with homology to bacterial

ribosomal proteins and those that are new and that can be unique to different organisms (Smits *et al.*, 2007; Rackham and Filipovska, 2013). There is a large variation in the proteins present in the mitochondrial ribosomes of different organisms. A number of these mitochondrial-specific ribosomal proteins are thought to play additional roles in the cell or to coordinate mitochondrial translation with other cellular processes. These include two SSU proteins that have been reported to play a role in apoptosis. A number of the ribosomal proteins in mammals are posttranslationally modified and these modifications appear to play an important regulatory role in the synthesis of the respiratory chain complexes (Koc and Koc, 2012).

Cryo-EM studies on bovine and porcine mitochondrial ribosomes (Agrawal and Sharma, 2012; Greber *et al.*, 2014; Kaushal *et al.*, 2014) indicate the presence of several interesting features (Figure 3). These ribosomes have a porous structure with several large masses protruding from a main compact globular core. No E-Site for deacylated tRNA as it leaves the ribosome is observed, a feature that distinguishes these ribosomes from bacterial and eukaryotic cytoplasmic ribosomes. There is a gate-like structure at the entrance to the mRNA-binding channel which may be required for the stable binding of the leaderless mRNAs during initiation. The polypeptide exit tunnel is quite unusual and readily allows premature access to the solvent before the exit site, suggesting an unusual nascent-polypeptide exit mechanism. All of the products of mammalian mitochondrial protein synthesis are inserted into the inner membrane of the organelle. The unusual structure near the exit tunnel may be involved in the interaction of the ribosome with the membrane and with the insertion of the polypeptide products into the hydrophobic core of the membrane (Agrawal and Sharma, 2012).

Perhaps the most unusual ribosomes investigated to date are those present in the kinetoplast of the Trypanosomes (Sharma *et al.*, 2009). These ribosomes have very small rRNAs, less than half the size of the bacterial rRNAs (Table 1) and a large number of proteins, most of which are unique to kinetoplast ribosomes. Their functions remain unknown. The cryo-EM map of these ribosomes (Figure 3) indicates that they have many of the structures expected of ribosomes, but this map has also revealed several unique features. Perhaps the most striking observation is the porosity of the particle. The space between the large and small subunits is quite large and shows many tunnels connecting it to the solvent. The mRNA-binding channel in the SSU is rich with unidentified proteins and the entrance to the channel is quite wide. The E-site appears to be

Table 1 Properties of mitochondrial ribosomes from various sources

Source of ribosomes	Sedimentation coefficient	Subunits	rRNAs	Proteins
Bacterial (Wittmann, 1986)	70S	30S and 50S	16S, 23S, and 5S	~54
Eukaryotic cytosol (Wittmann, 1986)	80S	40S and 60S	18S, 28S, and 5.8S	~82
Mammalian mitochondria (O'Brien and Kalf, 1967; Koc <i>et al.</i> , 2010)	55S	28S and 39S	12S and 16S ^a	~85
<i>S. cerevisiae</i> mitochondria (Grivell, 1995; Smits <i>et al.</i> , 2007)	74S	37S and 54S	15S and 21S	~78
Plant mitochondria (Bonen and Calixte, 2006)	~78S	~33S and 50S	18S, 25S, and 5S	~80
<i>Trypanosoma</i> kinetoplast (Agrawal and Sharma, 2012)	50S	28–30S and 40S	9S and 12S	~133

^aA second small unidentified RNA has been observed in the cryoEM structure of the porcine large subunit (Greber *et al.*, 2014). It is unlikely that this RNA is the 5S species or is derived from it (Lightowlers *et al.*, 2014).

Figure 3 Cryo-EM structures of bacterial and mitochondrial ribosomes. (a) The 70S *E. coli* ribosome, (b) the 55S bovine mitochondrial ribosome, and (c) the 50S ribosome from the protistan, *Leishmania tarentolae*, mitochondria. The rRNAs of the small subunit (SSU) and the large subunit (LSU) are colored orange and purple, respectively; the bacterial ribosomal proteins and proteins homologous to bacterial ribosomal proteins are colored green and aquamarine, respectively; the mitochondrial specific ribosomal proteins are colored yellow and blue. Landmarks of the SSU: h, head; mgt, mRNA gate; sh, shoulder; sp, spur. Landmarks of the LSU: CP, central protuberance; Sb, Stalk base. Reprinted from Agrawal, R.K., Sharma, M.R., 2012. Structural aspects of mitochondrial translational apparatus. Current Opinion Structural Biology 22, 797–803, with permission from Elsevier.

absent as observed in the mammalian mitochondrial ribosome. The polypeptide exit tunnel in the LSU has two openings as observed in mammalian mitochondrial ribosomes. The most highly conserved region of the ribosome is the peptidyl transferase center of the LSU.

Mechanism of Mitochondrial Protein Biosynthesis

Introductory Comments

Protein synthesis in mitochondria follows the same basic steps seen in bacterial and eukaryotic cytoplasmic translational systems. The process is divided into four major stages – initiation, elongation, termination and ribosome recycling. Given the presumed prokaryotic origin of mitochondria, it is expected that the process of protein synthesis in this organelle will be more closely related to that of bacteria than to that of the eukaryotic cell cytoplasm. This idea is borne out by studies of the translational machinery; however, there are a number of interesting and fundamental differences between mitochondrial and bacterial translation. Further, there are clearly distinct differences in how this process takes place in the mitochondria of different organisms. The most detailed studies have been carried out with the mammalian and yeast mitochondrial systems as summarized below.

Initiation

Mammalian mitochondrial system

During initiation, the start site on the mRNA is selected; the initiator tRNA is placed at the P-site of the ribosome and the reading frame on the mRNA is established. In standard translational systems, there are two tRNAs for methionine, one

for initiation and the second for elongation. Mammalian mitochondria are unusual in having a single tRNA^{Met}. A portion of this tRNA becomes formylated and the fMet-tRNA formed is used in chain initiation. The importance of formylation for initiation is illustrated by the serious medical effects arising from mutations in the methionyl-tRNA transformylase (Tucker *et al.*, 2011). The remainder of the tRNA remains as Met-tRNA and participates in elongation. The regulation of this partitioning is not currently understood.

Investigations into the mechanism of initiation indicate that two initiation factors (IFs) are present in mammalian mitochondria, initiation factor 2 (IF2_{mt}) and initiation factor 3 (IF3_{mt}). Based on the translational mechanism of bacteria, one would expect a third factor, initiation factor 1, IF1. However, in mammalian mitochondria, IF2_{mt} serves the function of both IF1 and IF2 (Gaur *et al.*, 2008). In the current model (Figure 4), initiation takes place through a number of discrete steps: (1) IF3_{mt} interacts with 55S ribosomes, forming a transient [IF3_{mt}:55S] complex. (2) The 39S subunit dissociates leading to the formation of an IF3_{mt}:28S complex. (3) IF2_{mt}:GTP binds to the small subunit followed by (4) the binding of the fMet-tRNA and mRNA. When the first 17 nucleotides of the mRNA have slid through the mRNA entrance gate, the movement of the mRNA pauses. During this pause, IF2_{mt}:GTP promotes the binding of fMet-tRNA to the ribosome. If there is an AUG or AUA codon exposed in the P-site, codon/anticodon interactions between the fMet-tRNA and the start codon lead to a stable initiation complex (Christian and Spremulli, 2010) locking the mRNA into place. If no codon/anticodon interactions can form due to a lack of fMet-tRNA or due to the absence of a 5' start codon, the inspection step fails and the mRNA resumes sliding through the small subunit and eventually dissociates. (5) With both mRNA and fMet-tRNA bound to the 28S subunit, the 39S subunit joins the initiation

Figure 4 Model for the initiation of protein synthesis in mammalian mitochondria. The steps are described in detail in the text. Reprinted from Christian, B.E., Spemulli, L.L., 2012. Mechanism of protein biosynthesis in mammalian mitochondria. *Biochimica et Biophysica Acta, Gene Regulatory Mechanisms* 1819, 1035–1054, with permission from Elsevier.

complex, GTP is hydrolyzed to GDP by IF2_{mt} and the initiation factors are released. The resulting 55S initiation complex can then enter the elongation process.

Initiation in yeast mitochondria

The mechanism of translational initiation in yeast mitochondria is quite different from that observed in mammals (Herrmann *et al.*, 2013). Initiation factors corresponding to IF2_{mt} and IF3_{mt} have been identified. While the gene for *S. cerevisiae* IF2_{mt} can be readily identified by homology searches, yeast IF3_{mt} (Aim23p) is very different in sequence from mammalian IF3_{mt}. It was not identified until highly sensitive alignment methods were used (Atkinson *et al.*, 2012). No factor equivalent to IF1 has been identified biochemically nor is a gene corresponding to this factor identifiable in the yeast genome. Unlike animal mitochondrial mRNAs, yeast mitochondrial mRNAs have long 5' UTR's (Figure 1). They do not have a Shine/Dalgarno sequence and the mechanism by which the start codon is recognized is unknown. A Met-tRNA transformylase has been identified, but unlike human mitochondria, yeast mitochondria can initiate protein synthesis with an unformylated Met-tRNA under some circumstances.

One of the most interesting features of translational initiation in yeast mitochondria is the requirement for nuclear-encoded mRNA-specific translational activator proteins. Genetic studies in *S. cerevisiae* have demonstrated that there are specific components that interact with individual mitochondrial mRNAs or ribosomes to control the level of synthesis of proteins encoded within the mitochondrial genome (Herrmann *et al.*, 2013). These factors have the ability to

recognize and bind to the 5' UTR of their specified mRNA (Figure 5). They also bind mitochondrial ribosomes and promote the interaction of the translational machinery with the inner membrane facilitating the insertion of the polypeptide products into the assembling respiratory chain complexes. It is also possible that some of these factors interact directly with the nascent chain and promote its incorporation into the appropriate complex. Mitochondrial ribosomes are strongly associated with the inner membrane. This interaction is facilitated in part by proteins such as Oxa1p which interact with the large subunit near the exit tunnel and may also interact with the nascent chain. An understanding of the precise mechanism by which these factors are involved in translational activation and membrane insertion must await the development of an *in vitro* translational system from this organelle.

Polypeptide Chain Elongation

The mechanism of chain elongation in mitochondria has significant similarities to the process in bacteria. In general, this phase of translation has been more highly conserved during evolution than either initiation or termination. The steps involved have been extensively studied only in the mammalian mitochondrial system (Spemulli *et al.*, 2004; Christian and Spemulli, 2012) and are outlined in Figure 6. In the first step, a ternary complex EF-Tu_{mt}-GTP:aa-tRNA enters the decoding site (A-site) of the ribosome and, if cognate codon:anticodon interactions can take place, it is stably bound (Step 1). Following selection, the GTP is hydrolyzed by EF-Tu_{mt} with the

Figure 5 Role of trans-acting factors in yeast mitochondria during translational initiation. Initiation of translation on yeast mitochondrial mRNAs requires the cooperative action of mRNA-specific translational activators. A number of these factors bind to the 5' end of the mRNA. They also appear to bind to the small subunit of the ribosome. They are often found associated with the inner membrane of the mitochondrion and may be directly involved in tethering the ribosome to the membrane. This interaction ensures that mitochondrial translation occurs at or near the membrane to allow the protein products to be inserted into the respiratory chain complexes. IMS, intermembrane space. Reprinted from Herrmann, J.M., Woellhaf, M. W., Bonnefoy, N., 2013. Control of protein synthesis in yeast mitochondria: The concept of translational activators. *Biochimica et Biophysica Acta* 1833, 286–294, with permission from Elsevier.

ribosome acting as the GTPase activating protein. $\text{EF-Tu}_{\text{mt}}\text{:GDP}$ is released (Step 2). In most mitochondrial systems including those from mammals, plants, and many fungi EF-Ts_{mt} acts as a guanine nucleotide exchange factor and displaces the GDP forming an $\text{EF-Tu}_{\text{mt}}\text{:EF-Ts}_{\text{mt}}$ complex (Step 3). Binding of GTP releases EF-Ts_{mt} leading to the formation of $\text{EF-Tu}_{\text{mt}}\text{:GTP}$ (Step 4) allowing another ternary complex to form. One interesting exception to this process occurs in *S. cerevisiae* mitochondria which do not have a factor corresponding to EF-Ts . In the yeast system, EF-Tu_{mt} binds guanine nucleotides very weakly obviating the need for the nucleotide exchange factor. In Step 5, the ribosome itself catalyzes peptide bond formation leaving a deacylated tRNA in the P-site and the peptidyl-tRNA in the A-site. Mitochondrial Elongation Factor G1 (EF-G1_{mt}) catalyzes the translocation step removing the deacylated tRNA from the P-site and moving the peptidyl-tRNA from the A-site to the P-site (Steps 6 and 7). In the mammalian mitochondrial system, the ribosomes do not appear to have an exit site (E-site) and the deacylated tRNA is thought to leave the ribosome during the translocation step.

Termination of Protein Synthesis and Ribosome Recycling in Mitochondria

From a mechanistic perspective, the best studied mitochondrial termination system is that from mammals ([Richter et al.](#),

Figure 6 Elongation of protein synthesis in mitochondria. The steps are described in detail in the text. Reprinted from Christian, B.E., Spremulli, L.L., 2012. Mechanism of protein biosynthesis in mammalian mitochondria. *Biochimica et Biophysica Acta, Gene Regulatory Mechanisms* 1819, 1035–1054, with permission from Elsevier.

2010; Lightowlers and Chrzanowska-Lightowlers, 2010). When mitochondrial DNA sequences were analyzed, it became clear that both UAA and UAG serve as stop codons while the standard UGA stop codon codes for tryptophan. Two reading frames end in AGA and AGG and these codons were initially believed to function as additional stop codons rather than as arginine codons. However, it is now thought that a -1 frame-shift during termination leads to the use of a UAG codon for termination in these mRNAs. Thus, only UAA and UAG actually represent stop codons in mammals.

Recent models for chain termination and ribosome recycling (Figure 7) suggest that when a stop codon arrives at the A-site of the translating ribosome, it is recognized by a release factor designated mtRF1a bound to GTP (Step 1). This binding event triggers the peptidyl transferase center on the large subunit to hydrolyze the peptide from the tRNA in the P-site releasing it as a completed product (Step 2). This step leaves a 55S ribosome:mRNA:tRNA complex which must be disassembled allowing the reuse of the components. This recycling step is carried out by the combined action of the mitochondrial ribosome recycling factor (mtRRF also designated RRF1_{mt}) and a translocase (EFG2_{mt} also referred to as RRF2_{mt}) related to EF-G1_{mt} used in chain elongation (Steps 3 and 4).

In yeast as in humans, two codons (UAA and UAG) function as stop signals. Both are recognized by mRF1

corresponding to the human mtRF1a. Like other mitochondrial systems, yeast mitochondria have factors corresponding to RRF1_{mt} and EFG2_{mt}. The overall mechanism of chain termination is expected to be similar to that observed in mammalian mitochondria.

Future Directions

In animals all of the products of mitochondrial protein synthesis are inserted into the respiratory chain complexes in the inner membrane. A similar observation holds true for most of the products in the mitochondrial translational systems of plants and the lower eukaryotes. Other subunits of these complexes are encoded in the nuclear genome, synthesized in the cell cytoplasm and imported into the mitochondrion for assembly into the respiratory chain complexes. Mitochondrial protein synthesis must certainly be regulated and coordinated with the expression of nuclear genes and with the assembly of the multi-subunit complexes. How this is accomplished remains to be elucidated.

Mitochondrial ribosomes are associated with the inner membrane allowing the incorporation of the nascent chain into the membrane. In yeast several proteins, including Oxa1p, have been identified that play a role in this process (Bonnefoy *et al.*, 2009). However, little is known about the details of how

Figure 7 Termination of mitochondrial translation and ribosome recycling. The steps are described in the text although many of the details remain to be elucidated. The ? indicates that it is unclear at the present time which release factor carries out this step. Reprinted from Christian, B. E., Spremulli, L.L., 2012. Mechanism of protein biosynthesis in mammalian mitochondria. *Biochimica et Biophysica Acta, Gene Regulatory Mechanisms* 1819, 1035–1054, with permission from Elsevier.

this interaction occurs and how it participates in the assembly of the respiratory complexes. Even less information is available in mammalian systems, and an understanding of the integration of mitochondrial translation with the physiology of the cell will require the identification and characterization of additional factors.

Glossary

Chaperone A protein which assists another protein in some way, usually to block inappropriate protein–protein interactions.

Consensus sequence An amino acid sequence required for a given posttranslational modification.

Cys-palmitoylation A reversible lipid modification of proteins that occurs in the secretory pathway (endoplasmic reticulum and Golgi apparatus), used for membrane targeting.

Genome-wide association studies Approach that involves genome screening to find genetic variations associated with a particular disease.

Heparan sulfate proteoglycan A core protein containing heparan sulfate chains (a linear sugar) which is present on the cell surface or in the extracellular matrix

N-glycosylation Attachment of a sugar chain to asparagines present in the glycosylation consensus sequence Asn-X-Ser.

Sulfation A posttranslational modification of secretory proteins consisting of the addition of a sulfate group to a tyrosine residue.

Transfection To introduce DNA into a cell to be expressed, usually performed together with a specialized lipid chemical.

Transmembrane domain A region of a protein capable of traversing the plasma membrane; normally an α -helix.

Zymogen An inactive enzyme precursor; also termed 'proenzyme.'

Introduction to Regulated Proteolysis

Activation of proteins via proteolytic maturation is a common mechanism used by cells to deploy specific biological activities in a defined temporal and spatial manner. Examples of proteolytic activation occur in all cellular compartments and in all tissues. Probably the most well-recognized example is the activation of pancreatic trypsinogen by the intestinal enzyme enterokinase, which prevents premature- and possibly destructive-production of active trypsin until it reaches the portion of the digestive tract in which it carries out degradative cleavage of nutritive proteins: the upper intestine. Another example of controlled protease action is the activation of cytoplasmic enzymes known as caspases, which exist normally as precursors activated by various messenger systems; these enzymes carry out proteolytic actions on mitochondrial and other proteins that ultimately result in cell death ('apoptosis').

However, proteolytic activation is not restricted to proteases themselves; many structural proteins are activated by proteolytic maturation. One of the most well-known examples is the cleavage of fibrinogen into fibrin, the protein which forms blood clots. While blood clot formation and dissolution involve protease cascades in which one protease activates another in exponential manner, the final substrate is not a protease but a structural protein. Another example of structural protein activation by proteolysis is the cleavage of procollagen to collagen, the scaffold of the extracellular matrix; this cleavage takes place only outside the cell, as intracellular formation of collagen fibrils would be damaging to the structural integrity of the cell. On the other hand, an example of a nonstructural proteolytic activation event is the maturation of protease-activated receptors by circulating proteases; this cleavage results in the formation of a new N-terminus which

acts as ligand for the receptor, thus activating it and triggering an intracellular signaling mechanism.

These few examples highlight the many ways in which proteases are used to control biological processes by proteolytic activation of specific substrates. In this article, we will describe in depth the regulatory proteases that are used to generate peptide signaling molecules, with a special emphasis on the prohormone convertases PC1/3 and PC2. We will present information on their biochemical properties, as well as the substrates they cleave, and how they are regulated. Lastly, we will discuss their relationship to disease states, and how human genetic studies have helped us understand their contribution to diseases states.

The Proprotein Convertases

The family of eukaryotic proprotein convertases, serine proteases with a subtilisin-like arrangement of the catalytic triad, originated with the discovery of the yeast proteinase Kex2 in 1988 (Fuller *et al.*, 1989a). A search for vertebrate homologs of Kex2 led the Thorner group to a human homolog (Fuller *et al.*, 1989b) at about the same time as the discovery by the group of van de Ven that the *fes* upstream region ('fur'), interrupted in lymphoma, encodes a sequence with strong homology to the Kex2 protease (van de Ven *et al.*, 1990); the protein that encodes this activity was therefore named furin. During the following decade, six other family members were discovered: PC2, PC1/3 (PC1; PC3; sPC3), PACE4, PC4, PC5/6, and PC7 (PC8; LPC). Alternative names used in early articles are shown in parentheses; the protein names used here were agreed upon at a Gordon Conference in 2004 (Fugere and Day, 2005). All of these enzymes cleave precursor proteins at basic residue

motifs. This article will not concern itself with another eukaryotic subtilase, PC9, which does not exhibit specificity for paired basic residues, and which has been recently amply reviewed (Seidah *et al.*, 2013, 2014; Seidah, 2013).

All convertases contain four domains in addition to the signal peptide (Figure 1). These include the propeptide, involved in intramolecular chaperoning; the catalytic domain, which carries out catalysis; an interesting novel structure called the 'P' or 'homo B' domain; and a C-terminal section, which, for certain family members, can contain a transmembrane domain. The order of the residues in the catalytic triad which accomplishes substrate cleavage, Asp, His, and Ser, is similar to that of the bacterial enzyme subtilisin; for this reason, this family of enzymes is known as the eukaryotic subtilases. The propeptide is thought to be required for efficient folding of the enzyme during synthesis, serving as an intramolecular chaperone. The P domain has only been studied for a few enzymes, but seems to contribute to enzymatic properties and is clearly important to enzyme stability since truncation of this domain by even a few residues results in instability and intracellular degradation. Lastly, the C-terminal domains, including the cytoplasmic segment which is present in enzymes containing a transmembrane domain (furin, PC5/6, and PC7), are thought to be involved in intracellular trafficking of the PCs.

In this article, we will discuss the expression, regulation, and functional characteristics of each of the convertases in turn, focusing in depth on the two convertases involved in the production of peptide hormones from precursors, PC1/3 and PC2.

Furin (*PCSK3*)

General Properties

Furin, the original founder of the mammalian subtilase family (van de Ven *et al.*, 1990), is now known to be involved in the cleavage of a wide variety of proteins within the constitutive secretory pathway and is ubiquitously expressed (Molloy *et al.*, 1999). At this time, over 2000 articles have been written on furin, making it the best-studied member of the family of proprotein convertases. The gene encoding furin is known as *PCSK3* and it is located on chromosome 15 in humans. Five different transcripts (spliced forms) of furin have been reported, with transcript A (resulting in a protein of 794 amino acids) most commonly expressed (Hatsuzawa *et al.*, 1990; Seidah *et al.*, 1991). The role of so many different transcripts is as yet unclear.

Furin is one of only three proprotein convertases possessing a transmembrane domain/cytoplasmic tail in the C-terminal region (the others are PC5/6B and PC7). This feature enables furin to bind cytoplasmic routing proteins and to cleave its substrates in three distinct subcellular compartments, the *trans*-Golgi network (TGN); the plasma membrane, and the endosomal compartment following its retrieval from the plasma membrane. Molloy *et al.* (1999) have written an excellent article on furin action in various compartments. In addition to these domains, the C-terminal region of furin is particularly rich in cysteine residues (Figure 1); the function of these cysteines is currently unknown.

Figure 1 Schematic representation of human proprotein convertases. The subtilisin/kexin-like proprotein convertases family is composed of seven members: PC1/3 (*PCSK1*), PC2 (*PCSK2*), furin (*PCSK3*), PC4 (*PCSK4*), PC5/6 (*PCSK5*), PACE4 (*PCSK6*), and PC7 (*PCSK7*). All convertases contain four main domains (a prodomain, a catalytic domain, a P domain, and a C-terminal (Ct) domain of variable length) and a signal peptide (SP). The catalytic domain is the most conserved region among proprotein convertases and includes the Asp-His-Ser (D-H-S) catalytic triad typical of serine proteases. Note that PACE4 exhibits an unusually long signal peptide in comparison to the other convertases. In the case of furin, PC5/6 and PACE4, the C-terminal domain is rich in Cys residues (highlighted as asterisks). This Cys-rich domain has been shown to be involved in the binding of PC5/6 and PACE4 to proteoglycans at the cell surface. PC5/6 is the only family member that undergoes major alternative splicing, resulting in the two isoforms PC5/6A and PC5/6B that differ considerably in the length of their C-terminal tails.

Enzymatic Properties and Substrate Cleavage

Furin exhibits specificity for a basic residue motif consisting of Arg-X-Arg, where the middle residues are also often basic residues. The enzyme has a neutral pH optimum, requires calcium, and its propeptide is rapidly cleaved from its precursor in the endoplasmic reticulum, though the propeptide remains attached until late in the secretory pathway (Anderson *et al.*, 1997). Some internal cleavage ('shedding') of the membrane anchor occurs when the enzyme reaches the cell surface; the enzyme that performs this reaction has not yet been identified. Like other convertases, furin requires autocatalytic cleavage of its prodomain for activation (Anderson *et al.*, 1997). This process occurs in two different steps and is compartment-specific. First, the prodomain is rapidly cleaved in the endoplasmic reticulum at neutral pH; the propeptide remains attached. During trafficking within the secretory pathway, propeptide removal occurs under mildly acidic pH conditions, thus ensuring that furin acts in a compartment-specific manner.

Because of its complicated cellular itinerary, furin is capable of cleaving a wide range of precursor proteins. Some of the more notable substrates of furin include blood proteins, such as albumin, secreted from the liver; matrix metalloproteinases (MMPs) such as MMP2 and 9; and bacterial toxins such as those produced by the anthrax and *Pseudomonas* bacteria (reviewed in Molloy *et al.* (1999)). Thus far the crystal structure of furin is the only known structure of a member of the proprotein convertase family in higher animals (Henrich *et al.*, 2003).

Physiological Significance of Furin

The furin knockout mouse dies early during embryonic development; death is thought to derive from an inability to make growth factors (Roebroek *et al.*, 1998). Interesting tissue-specific knockouts have been made (e.g., Louagie *et al.*, 2008) which show unexpected cellular roles for this enzyme in identifying new substrates. Furin is not, however, required for tissue viability after development, as tissue-specific knockouts exist (Roebroek *et al.*, 2004; Creemers and Khatib, 2008), as do cell lines which do not express furin (e.g., LoVo; Takahashi *et al.*, 1993).

Overexpression of human furin is correlated with increased carcinogenic potential (Mbikay *et al.*, 1997; Bassi *et al.*, 2000; Thomas, 2002) and furin upregulation in tumors has been associated with increased tumor aggressiveness (Bassi *et al.*, 2001). High furin activity has been related to increased processing of the substrates membrane type 1-MMP (MT1-MMP) (Bassi *et al.*, 2001) and insulin-like growth factor-1 (IGF1) as well as IGF1 receptor present on the surface of tumor cells (Khatib *et al.*, 2001). Administration of furin inhibitors blocks tumor metastasis in mice (Khatib *et al.*, 2001; Bassi *et al.*, 2001). A number of synthetic inhibitors against furin have been recently generated using the crystal structure of furin (Jiao *et al.*, 2006; Coppola *et al.*, 2008; Komiyama *et al.*, 2009; Becker *et al.*, 2010). Interestingly, these furin inhibitors have been also proposed for the treatment of viral and pathogenic infections (Komiyama *et al.*, 2005; Ozden *et al.*, 2008).

Prohormone Convertase 1/3 (PCSK1)

General Properties

Prohormone convertase 1/3 (PC1/3), formerly known as PC1, was one of the earliest PCs discovered (Smeekens *et al.*, 1991; Seidah *et al.*, 1991). This enzyme is predominantly located in neuroendocrine tissues (such as brain, pituitary, adrenal, and pancreas) (Hoshino and Lindberg, 2012). PC1/3 specifically cleaves peptide hormone precursors at the carboxyl side of the amino acids lysine or arginine. This enzyme recognizes a dibasic pair of amino acids, generally lysine-arginine, although rarely a single arginine residue can be used. PC1/3-mediated cleavage of precursor proteins occurs almost exclusively in the TGN and the secretory granules of neuronal and endocrine cells, where it cleaves a wide variety of neuropeptides and peptide hormones, including pro-opiomelanocortin (POMC), proinsulin, proglucagon, parathyroid hormone, proenkephalin, and prodynorphin (reviewed in Hoshino and Lindberg (2012)).

In the brain, PC1/3 is highly expressed in the hypothalamus, for example, in POMC-expressing neurons. In peripheral tissues, its expression is especially strong in pancreas (mainly in the β cells of the islets); adrenal medulla; adenohypophysis; thyroid; and small intestine (where it resides in the enteroendocrine cells). Figure 2 shows the PC1/3-mediated processing of POMC, proinsulin, and proglucagon. In the case of POMC, PC1/3 cleaves the protein at two different dibasic residue sites, producing three different peptides: the N-terminal region of POMC, adrenocorticotrophic hormone (ACTH), and β -lipotropin (β -LPH) (Zhou and Mains, 1994). In pancreatic β cells, PC1/3 initiates the processing of proinsulin by cleaving the bond between the β -chain and the connecting peptide ('C peptide') (Smeekens *et al.*, 1992). In the enteroendocrine cells of the small intestine, PC1/3 enzymatic activity results in the processing of proglucagon to glicentin, GLP-1, and 2 (GLP-2) (Rouille *et al.*, 1995). Note that in this case PC1/3 is able to cleave the precursor at a single arginine residue rather than the double basic residues which are much more common consensus sequences.

PC1/3 Maturation in the Regulated Secretory Pathway

The *PCSK1* gene consists of 14 exons that encode the 753-amino acid precursor preproPC1/3. The signal peptide is co-translationally removed in the endoplasmic reticulum, resulting in an inactive proPC1/3 zymogen (97 kDa) formed by the four different domains described earlier (Figure 3): (1) a prodomain involved in intramolecular chaperoning and early enzyme inhibition (Baker *et al.*, 1993; Rabah *et al.*, 2006), (2) a catalytic domain, which contains the catalytic triad Asp-His-Ser which accomplishes catalysis, (3) a P domain critical to convertase maturation and which is known to contribute to enzymatic properties (calcium binding, low pH dependence, and substrate specificity) (Zhou *et al.*, 1998), and (4) a C-terminal domain, involved in targeting PC1/3 to the secretory granules and in enzyme stability and activity (Rovere *et al.*, 1999; Bernard *et al.*, 2003).

After translation, the PC1/3 precursor proPC1/3 rapidly cleaves its own prodomain within the endoplasmic reticulum

Figure 2 Initial prohormone processing by PC1/3. In POMC-expressing cells the POMC precursor is cleaved by PC1/3 at two KR (lysine-arginine) dibasic sites. ACTH can be secreted (anterior lobe of the pituitary gland) or be further processed by PC2 (intermediate lobe of the pituitary gland) (see Section on PC2). In pancreatic β cells, PC1/3 initiates the cleavage of proinsulin by catalyzing the breakage of the bond between the B chain and the C peptide at an arginine-arginine site. In the endocrine L cells of the small intestine (which lack PC2), PC1/3 catalyzes the cleavage of proglucagon at three dibasic sites (RR, KR) and one arginine (R), producing glicentin and the glucagon-like peptides (GLP) 1 and 2.

Figure 3 The structure of PC1/3. The preproPC1/3 precursor is co-translationally converted into proPC1/3 during synthesis. In the endoplasmic reticulum (ER), the prodomain (Pro) rapidly undergoes autocatalytic cleavage. In the TGN the prodomain is finally removed, initiating activation of this enzyme. The 87-kDa form is catalytically active, but undergoes additional processing within the C-terminal (Ct) tail in the secretory granules (SG), generating more active truncated forms (74/66 kDa) with somewhat different biochemical properties.

(Lindberg, 1994; Goodman and Gorman, 1994; Zhou and Mains, 1994). The cleaved prodomain remains bound to the rest of the protein, participating in folding and later activation of this protein in the Golgi apparatus and inhibiting the PC1/3 enzymatic activity during the transition between the endoplasmic reticulum and the Golgi and the protein maturation (Rabah *et al.*, 2006). In the TGN, the prodomain finally dissociates, and PC1/3 assumes its active 87-kDa form (Figure 3). In addition to prodomain cleavage and removal, PC1/3 must also undergo certain posttranslational modifications, such as N-glycosylation (Benjannet *et al.*, 1993) for correct folding and maturation within the secretory pathway; the enzyme is also sulfated (Benjannet *et al.*, 1993), though the role of this posttranslational modification is not known.

In comparison to other convertases, such as PC2 and furin, the 87-kDa form of PC1/3 is considerably less active (Zhou and Lindberg, 1993); its autocatalytic processing at the C-terminal domain in the secretory granules results in much more active, but unstable, forms of 74 and 66 kDa (Figure 3) (Zhou and Lindberg, 1994). After cleavage of the C-terminal tail, 74- and 66-kDa forms are able to act at a lower and narrower pH range (5–5.5) (Zhou and Lindberg, 1993), in contrast to the broader pH optimum (5–6.5) of the 87-kDa protein (Zhou and Lindberg, 1994). Like other convertases, PC1/3 requires calcium for enzymatic activity (mM range), and the truncated forms exhibit somewhat greater calcium

dependence (Zhou and Lindberg, 1993, 1994). A recent study has found that in mammalian cells and tissues a high percentage of 87-kDa PC1/3 is present as inactive oligomers and aggregates, whereas 74/66-kDa forms exist primarily in an active monomeric state (Hoshino *et al.*, 2011).

ProSAAS is a neuroendocrine PC1/3 binding protein involved in endogenous inhibition of this enzyme within the regulated secretory pathway (Fricker *et al.*, 2000; Qian *et al.*, 2000; Fortenberry *et al.*, 2002). In endocrine cells, the majority of PC1/3-expressing cells—excepting pancreatic β cells—co-express high amounts of proSAAS protein, which suggests that proSAAS participates in the regulation of PC1/3 activity in neuronal and endocrine tissues (Fricker *et al.*, 2000). However, proSAAS is much more widely expressed in brain than is PC1/3, suggesting other actions (Lanoue and Day, 2001). ProSAAS has been recently shown to serve as a potent antiaggregant chaperone protein in blocking amyloid polypeptide fibrillation (Peinado *et al.*, 2013; Hoshino *et al.*, 2014). These data hint at a possible role for this protein in the development of neurodegenerative diseases involving aggregative processes.

Physiological Significance of PC1/3

In humans as well as in mice, the loss of PC1/3 activity is associated with an increase in circulating prohormone levels.

In humans, a (rare) deficiency in PC1/3 activity caused by inactivating mutations on both alleles has been related to early-onset obesity, diarrhea, diabetes, and hypogonadism (Jackson *et al.*, 1997, 2003; Farooqi and Volders, 2007; Yourshaw *et al.*, 2013; Martin *et al.*, 2013). Thus far, 17 patients exhibiting total or partial loss of PC1/3 activity (via the presence of inactivating mutations) have been reported (Jackson *et al.*, 1997, 2003; Farooqi and Volders, 2007; Yourshaw *et al.*, 2013; Martin *et al.*, 2013). The *PCSK1* mutations found in these individuals are summarized in Table 1. It is important to mention that 14 of the 17 subjects in this table are homozygous for the mutant PC1/3 allele, and in only three cases do individuals exhibit different inactivating mutations in each *PCSK1* allele (see Table 1 legend for further information). Interestingly, the G593R variant, which affects the removal of the prodomain and exit from the endoplasmic reticulum, is present in two of these 17 cases and was present in the original 1997 report of a *PCSK1* mutation; this is thus the most common of these rare mutations (Jackson *et al.*, 1997, 2003; Farooqi and Volders, 2007; Yourshaw *et al.*, 2013; Martin *et al.*, 2013).

Recently, individuals heterozygous for 8 non-synonymous mutations in PC1/3 that partially or totally reduce enzymatic activity have been identified (Creemers *et al.*, 2012). This screening, performed in lean and obese European cohorts (both adults and children), indicates that individuals in possession of just one mutant PC1/3 allele have a much higher risk of developing obesity (by 8.7 times). Recent genome-wide association studies showed that there are three common single nucleotide polymorphisms (SNPs) in *PCSK1* (rs6232, rs6234, and rs6235) strongly associated with obesity in European (Benzinou *et al.*, 2008; Kilpelainen *et al.*, 2009; Heni *et al.*, 2010; Rouskas *et al.*, 2012), Asian (Hsiao *et al.*,

2014), and Mexican populations (Villalobos-Comparan *et al.*, 2012). The SNPs rs6232, rs6234, and rs6235 encode for the N221D, Q665E, and S690T variants, respectively. Interestingly, the non-deleterious Q665E and S690T variants are very common in the population (~25%) and are also associated positively with the incidence of diabetes (Benzinou *et al.*, 2008; Heni *et al.*, 2010; Strawbridge *et al.*, 2011). Unlike the double substitution Q665E/S690T, which does not cause a significant loss of enzyme activity, the N221D mutation reduces PC1/3 activity (Benzinou *et al.*, 2008; Mbikay *et al.*, 2011; Pickett *et al.*, 2013). The recently reported *PCSK1* SNP rs1799904, encoding an R80Q mutation in the propeptide, also has a significant presence in the general population (0.87% minor allele frequency). Similarly to the N221D variant, this mutant exhibits partial loss of enzymatic activity (Pickett *et al.*, 2013).

In mice, total loss of the *PCSK1* gene does not result in increased body weight. In fact, homozygous animals are even smaller than control littermates, mainly because PC1/3 deficiency causes a decrease in growth hormone synthesis due to differences in the sequences of growth hormone between humans and mice (Zhu *et al.*, 2002). However, heterozygous PC1/3 null adult mice do show increased susceptibility to obesity (Zhu *et al.*, 2002; Mbikay *et al.*, 2007). In addition, mice homozygous for the N222D mutation, which results in a partial decrease in PC1/3 activity, are obese and exhibit impaired plasma insulin levels (Lloyd *et al.*, 2006). Interestingly, transgenic mice overexpressing the PC1/3 inhibitor proSAAS develop obesity and hyperglycemia, possibly due to inhibition of endogenous PC1/3 activity (Wei *et al.*, 2004). Conversely, proSAAS knockout mice are lean (Morgan *et al.*, 2010). All of these data point to an important role for PC1/3 and its binding protein, proSAAS, in body weight regulation.

Table 1 Human mutations reported in 17 individuals lacking PC1/3 activity

<i>PCS KI mutation</i>	<i>Mutation Type</i>	<i>PC1/3 domain</i>	<i>PC1/3 properties</i>
G209R	Missense	Catalytic domain	Retained in ER
P258T	Missense	Catalytic domain	Secreted but less active
S307L	Missense	Catalytic domain	Secreted but inactive
N423K	Missense	Pdomain	Secreted but less active
F548S	Missense	Pdomain	Secreted but inactive
G593R	Missense	P domain	Retained in ER
M1X	Nonsense	Signal peptide	Truncated
Y231X	Nonsense	Catalytic domain	Truncated
G250X	Nonsense	Catalytic domain	Truncated
Q337X	Nonsense	Catalytic domain	Truncated
Y343X	Nonsense	Catalytic domain	Truncated
R405X	Nonsense	Catalytic domain	Truncated
A213del	Deletion	Catalytic domain	Partially processed/low secretion
V450fsxl	Deletion	Pdomain	Truncated
A → C + 4(intron 5)	Splice site	Catalytic domain	Truncated
IVS8 + 1G > T	Splice site	Catalytic domain	—
IVS8 + 1G > A	Splice site	Catalytic domain	—

Note: Two of the missense mutants, G209R and G593R, are retained in the endoplasmic reticulum. The remainder of the missense variants, P258T, S307L, N423K, and F548S, are secreted but either display lower enzymatic activity, or are completely inactive. All nonsense mutations result in highly unstable truncated variants (due to a premature stop codon) lacking catalytic activity. The V450fsxl mutation in the frame shift site results in a truncated protein that lacks the P and CT domains. The A → C + 4 transversion in the donor splice site of exon 5 results in a premature stop codon in the catalytic domain. The splice site mutations IVS8 + 1G > T and IVS8 + 1G > A are located at the same acceptor nucleotide in intron 8, and are predicted to critically affect the correct splicing of the *PCSK1* gene. Whereas 14 of the 17 patients are homozygous for their mutations, three individuals have an inactivating mutation in each allele (G593R/A → C + 4; G250X/A213del; and G209R/P258T).

Prohormone Convertase 2 (PCSK2)

General Properties

The prohormone convertase 2 (PC2) is encoded by the gene known as PCSK2, and was the second convertase discovered (Smeekens and Steiner, 1990). Like PC1/3, PC2 is highly expressed in brain, pituitary gland, adrenal medulla, and pancreas and is a key activator of prohormones and neuropeptide precursors within the regulated secretory pathway of neuroendocrine cells. Within the brain, PC2 expression is rich in the hypothalamus, where it acts to cleave a variety of peptide precursors such as proCART (see table in reference Hoshino and Lindberg, 2012). In the pituitary gland, PC2 is mostly located in the intermediate lobe, where it also carries out the cleavage of ACTH to α -melanocyte-stimulating hormone (α -MSH) (Pritchard *et al.*, 2003; Tanaka, 2003). In the pancreas, PC2 is present exclusively in islet tissue, both in α and β cells (but mostly in α cells), where it participates in the synthesis of insulin and glucagon (Furuta *et al.*, 1998; Dey *et al.*, 2004). Note that depending on the tissue where a given precursor is produced, different peptides are generated; this is due to the tissue-specific expression of each convertase. For example, in the anterior lobe of the human pituitary gland, POMC is processed to ACTH but not to α -MSH; whereas, in the intermediate lobe PC2 is able to process ACTH to α -MSH (Figure 4; Pritchard *et al.*, 2003; Tanaka, 2003; Seidah *et al.*, 1999). In the β -cells of pancreatic islets, PC2 and PC1/3 are required for the complete processing of proinsulin. In this case PC2 cleaves the bond between the α -chain and the C peptide, generating insulin (Steiner, 2011). However, PC1/3 null mice can still produce some insulin (Zhu *et al.*, 2002), so it is clear

that functional redundancy must exist between the two prohormone convertases.

Similarly to PC1/3, PC2 is a calcium-dependent endoprotease with a low pH optimum. However, these properties differ considerably from that of PC1/3; the calcium requirement is much lower (micromolar range) and PC2 operates at a lower pH for catalysis, pH 5.0. Indeed, PC2 has the lowest pH optimum of the identified convertases. The substrate specificity of PC2 is also much broader than PC1/3; it is capable of cleaving precursors at a pair of basic residues (usually Lys-Arg or Arg-Arg), and even at a single basic residue if an upstream proline is present (Seidah and Prat, 2012). A number of synthetic non-peptide compounds with potent inhibitory action against PC2 have recently been described (Kowalska *et al.*, 2009; Vivoli *et al.*, 2012; Yongye *et al.*, 2013).

ProPC2 Maturation in the Regulated Secretory Pathway

Like PC1/3, proPC2 contains four different domains: the propeptide, the catalytic domain, the P domain, which is critical for both expression as well as zymogen cleavage (Zhou *et al.*, 1995), and a short C-terminal tail domain that seems to be responsible for granule targeting. PC2 is itself synthesized as a precursor protein, preproPC2, and requires proteolytic maturation for activation, a step where the neuroendocrine chaperone 7B2 plays an important role (Benjannet *et al.*, 1995a,b). In contrast to many of the convertases, PC2 does not require cleavage of its prodomain to exit the endoplasmic reticulum. In fact, the prodomain is involved in the binding of proPC2 to 7B2, a process which occurs after proPC2 folding in the endoplasmic reticulum. Once binding

Figure 4 POMC processing by the prohormone convertases 1/3 and 2. Prohormone convertase cleavage of POMC defines the final hormone that will be secreted from neuroendocrine tissues. PC1/3 cleaves POMC to produce β -LPH and ACTH and other peptides, whereas PC2, and only PC2, can further cleave ACTH to produce α -MSH and corticotrophin intermediate-like peptide (CLIP).

occurs, the 7B2/proPC2 complex exits this compartment and travels to the TGN. PC2 activity is thought to be endogenously inhibited by the C-terminal domain of 7B2 during trafficking through the secretory pathway, although overexpression of this domain alone does not decrease peptide processing (Fortenberry *et al.*, 1999). In the acidic environment of the TGN and secretory granules, 7B2 dissociates from proPC2 either before or during its autocatalytic activation via autocatalytic prodomain removal (Tanaka, 2003; Seidah and Chretien, 1999; Figure 5). Unlike PC1/3, PC2 is fully active without further C-terminal cleavage. Recent studies show that 7B2 facilitates proPC2 maturation by preventing its aggregation and inactivating oligomerization (Lee and Lindberg, 2008). Interestingly, 7B2 is much more widely distributed in neuronal and endocrine tissues when compared to the more limited distribution of PC2 (Seidel *et al.*, 1998). These studies raise the idea that 7B2 may possess additional functions other than assisting proPC2 trafficking. In this regard, it has been recently reported that 7B2 is capable of blocking the aggregation of amyloid-containing polypeptides (Peinado *et al.*, 2013; Helwig *et al.*, 2013).

Physiological Significance of PC2

Although PC2 null mice are viable and appear normal at birth, they display retarded growth (Scamuffa *et al.*, 2006). Analysis of these mice reveals chronic fasting hypoglycemia and a deficiency in circulating glucagon. Glucagon is produced in islet α -cells through cleavage of proglucagon by PC2, whereas in intestinal L cells GLPs with different profiles of bioactivity are produced through cleavage by PC1/3 (Hayashi, 2011). In humans, variants in the *PCSK2* gene sequence are associated with reduced insulin secretion in nondiabetic individuals (Jonsson *et al.*, 2012). Variants in the *PCSK2* gene have previously been also linked to type 2 diabetes in African (Leak *et al.*, 2007), Japanese (Yoshida *et al.*, 1995) and European (Jonsson *et al.*, 2012) individuals. However, linkage of *PCSK1* variants to obesity and diabetes is far more common than *PCSK2* variants, suggesting that the PC2 sequence may be more evolutionarily constrained.

Tumors of neuroendocrine origin display increased PC2 expression (Scopsi *et al.*, 1995). PC2 is also clearly expressed in pituitary adenomas, where it is associated with increased

Figure 5 Biosynthesis and maturation of PC2 during the secretory pathway. The signal peptide of preproPC2 is co-translationally removed in the endoplasmic reticulum (ER). The resulting product, proPC2, requires a long time to fold; when folded, it then binds to the secretory chaperone 7B2 (the intact 27-kDa form). 7B2 binding blocks proPC2 aggregation and is essential to maintain the competence of proPC2 for later activation in the secretory granules. Within the acidic environment of secretory granules, proPC2 is activated by autoproteolytic cleavage of the prodomain, and 7B2 (now present as the furin-cleaved 21-kDa form) dissociates from the complex. The presence of 7B2 is not required for proPC2 activation, an intramolecular process initiated by exposure to acid pH.

circulating levels of α -MSH. Also, PC2 expression is present in bronchial carcinoid tumors expressing ACTH, lung carcinomas, adrenomedullary tumors, and pheochromocytomas; PC2 has also been shown to be expressed in two breast cancer lines (Hoshino and Lindberg, 2012). Many neuroendocrine tumors also express 7B2 (reviewed in Mbikay and Seidah, 2001). Thus the expression of PC2 and 7B2 seems to be associated with a differentiated neuroendocrine phenotype.

Proprotein Convertase 4 (PCSK4)

The proprotein convertase 4 (PC4), discovered in 1992 (Nakayama *et al.*, 1992), has the most restricted expression pattern among all members of the family of convertases (Gyamera-Acheampong and Mbikay, 2009). In males, PC4 is expressed exclusively in the testis, where it is mainly located in the haploid spermatids and the sperm cells (Nakayama *et al.*, 1992; Seidah *et al.*, 1992; Torii *et al.*, 1993; Gyamera-Acheampong *et al.*, 2006). PC4 is also detected in spermatocytes and in the residual bodies engulfed by Sertoli cells (Gyamera-Acheampong *et al.*, 2006). PC4 is specifically located in the acrosomal granules and ridges of round and elongated spermatids, respectively. In sperm cells PC4 accumulates in the plasma membrane overlying the acrosome, where it is thought to participate in the fertilization process (Gyamera-Acheampong *et al.*, 2006; Iamsaard *et al.*, 2011). In females, the distribution of PC4 is limited to the ovary and placenta (Tadros *et al.*, 2001; Qiu *et al.*, 2005).

Thus far no data exist on the biosynthesis and trafficking of PC4 within the secretory pathway. Data on the biochemical properties of PC4 have been obtained *in vitro* by using purified recombinant protein after transfection into somatic cell lines (Basak *et al.*, 2008; Remacle *et al.*, 2008). Like all kexin-like convertases, PC4 is capable of cleaving peptide substrates after an arginine residue at a dibasic site (Lys-Arg and Arg-Arg) (Remacle *et al.*, 2008), but preferentially recognizes and cleaves the sequence motif Lys-X-X-Arg following the Arg residue, where X is any amino acid (Basak *et al.*, 2008, 1999, 2004). PC4 enzymatic activity requires neutral pH and mM calcium concentrations (Basak *et al.*, 1999).

Mutant male mice lacking PC4 display severely impaired fertility, and in the *PCSK4* null, spermatozoan capacity to fertilize eggs *in vitro* is significantly reduced (Mbikay *et al.*, 1997; Tardif *et al.*, 2012). The loss of PC4 activity in spermatozoa has been associated with altered processing of acrosin-binding protein (ACRBP), a sperm molecule involved in fertilization (Tardif *et al.*, 2012), which may represent the only known substrate of this enzyme. In addition, several groups have proposed that PC4 might be involved in fertilization via the activation of sperm surface proteins such as the metalloproteases ADAM-1, -2, -3, and -5 (Gyamera-Acheampong *et al.*, 2006; Basak *et al.*, 2004).

Paired Basic Amino Acid Cleaving Enzyme 4 (PACE4; PCSK6)

Like many other convertases, the paired basic amino acid cleaving enzyme 4 (PACE4), encoded by the gene *PCSK6*, has

a widespread tissue distribution, including cerebellum, heart, intestine, kidney, liver, and muscle (Kiefer *et al.*, 1991; Dong *et al.*, 1995). PACE4, discovered in 1991 (Kiefer *et al.*, 1991), is very similar to PC5/6 in many aspects. For example, both convertases can bind tissue inhibitors of metalloproteases and heparan sulfate proteoglycans at the cell surface or in the extracellular matrix via their C-terminal Cys-rich domains (Tsuji *et al.*, 2003; Nour *et al.*, 2005; Mayer *et al.*, 2008; Seidah *et al.*, 2008). Unlike other convertases, PACE4 and PC5/6 can be activated at the cell surface when they are in contact with heparan sulfate proteoglycans (Mayer *et al.*, 2008; Seidah *et al.*, 2008). In this case, the second cleavage of the prodomain, and the subsequent activation, occurs at the cell surface, restricting its activity to the cell surface and extracellular matrix: an example of regulated proteolysis.

In vitro, PACE4 processes the same substrates as other convertases such as furin and PACE5/6, exhibiting strong redundancy with these convertases (Seidah, 2011). *In vivo*, PACE4 (and also furin) is able to cleave Nodal, a secreted protein in the transforming growth factor β family, at the membrane (Mesnard *et al.*, 2011). Other proposed *in vivo* substrates are the metalloprotease ADAM-TS4 (Tortorella *et al.*, 2005), angiopoietin-like protein 3 (Liu *et al.*, 2010), a secreted protein that functions in angiogenesis, and the viral glycoprotein Vpr (Xiao *et al.*, 2008).

In mice, knockout of the PACE4 gene causes about 25% of homozygous mutant embryos to die prenatally with severe cardiac malformations, and the viable knockout mice display bone morphogenetic defects (Constam and Robertson, 2000). Interestingly, PACE4 and furin are overexpressed in the cartilage of patients with arthritis (Seidah and Prat, 2012), and inhibitors of these convertases have been added in cartilage explants for arthritis treatment (Byun *et al.*, 2010). PACE4/furin overexpression has recently been associated with the development of prostate and skin cancers (Bassi *et al.*, 2010; D'Anjou *et al.*, 2011). The inhibition of furin or PACE4 has been also proposed for the treatment of some viral and pathogenic infections (Seidah and Prat, 2012) as well as in cancer (Seidah and Prat, 2012; D'Anjou *et al.*, 2011; Levesque *et al.*, 2012).

Proprotein Convertase 5/6 (PCSK5)

The proprotein convertase 5/6 (PC5 or PC6; now known exclusively as PC5/6), was discovered in 1993 simultaneously by the Seidah and Nakayama (Nakagawa *et al.*, 1993; Lusson *et al.*, 1993) groups. This convertase can be alternatively synthesized as one of two transcripts, one bearing a transmembrane domain (PC5B/6B); and one lacking such a domain (PC5A/6A). Like furin and PACE4, this enzyme also has a widespread tissue distribution. While PC5/6A is a soluble 915-aa protein with a C-terminal domain rich in Cys residues, the PC5/6B form has an extended C-terminal tail of almost 1000 residues that includes a transmembrane domain (Nakagawa *et al.*, 1993). In brain PC5/6 mRNA has been found in regions rich in neuropeptides, including cortex, hippocampus, and hypothalamus. PC5/6 is also expressed in adrenal cortex, ovary, pituitary (anterior lobe), lung, and thyroid (Lusson *et al.*, 1993). PC5/6B transcript expression is especially high in

small intestine and kidney (Seidah, 2011). Like PACE4, PC5/6 is also activated at the cell surface where it contacts heparan sulfate proteoglycans (Mayer *et al.*, 2008). However, because of its transmembrane domain, PC5/6, but not PACE4, is able to cycle from the cell surface back to the TGN through endosomes (Xiang *et al.*, 2000), similarly to furin and PC7 (see corresponding sections).

As discussed in the previous section, certain redundancies between the substrate specificity of the convertases furin, PACE4, PC5/6, and PC7 have been demonstrated in a number of *in vitro* experiments, often leading to difficulty in identification of the protease responsible for a particular event. *In vivo*, one known PC5/6 substrate is growth differentiation factor 11, GDF11 (also known as bone morphogenetic protein 11, BMP-11) (Essalmani *et al.*, 2008). Interestingly, PC5/6 deficiency causes a similar phenotypic pattern as GDF11 knockout, with death shortly after birth, the absence of kidneys and tails, and spinal abnormalities (Essalmani *et al.*, 2008). PC5/6 knockout mice also exhibit GDF11-independent phenotypes, suggesting that the lack of this convertase also affects the processing of other substrates. In addition, PC5/6 mediates the proteolytic activation of α -integrins (Paule *et al.*, 2012) and the phosphoprotein EBP50 (Heng *et al.*, 2011) in endometrial cells, suggesting a key role of this convertase in successful embryo implantation.

In human colon carcinoma tissue, PC5/6 expression is significantly lower than in the adjacent normal tissues (Sun *et al.*, 2009), and PC5/6 expression is not detected in breast tumors (Cheng *et al.*, 1997). These analyses suggest this convertase could have a protective role in tumor growth. In agreement with this idea, crossing mutant mice lacking PC5/6 only in enterocytes together with $Apc^{min/+}$ mice (animals with a point mutation in the *Apc* gene that are used as a model for the human disease familial adenomatous polyposis) has revealed that the loss of PC5/6 both increases tumor number and causes premature mortality (Sun *et al.*, 2009). The interesting paradox of furin and PACE4 acting in a pro-carcinogenic fashion while PC5/6 expression is anticarcinogenic has been previously discussed (Seidah, 2011).

Proprotein Convertase 7 (PCSK7)

Human proprotein convertase 7 (PC7; also known as PC8 and LPC) was first identified as a sequence within a chromosome breakpoint region in lymphoma tissue (Meerabux *et al.*, 1996). While PC7 is thought to be the most ancestral of the basic amino acid-specific convertases, only recently several of its physiological functions have been clarified. Several studies have shown a widespread expression of PC7 mRNA in nearly all tissues and several cell lines (Seidah *et al.*, 1996). Specifically, abundant expression of PC7 has been found in colon, kidney, duodenum, and heart in adult mouse, which indicates that PC7 may exert multiple physiological functions. Similarly to furin, PACE4 and PC5/6, PC7 cleaves its substrates following specific arginine residues both *in vitro* and within cells (Rousselet *et al.*, 2011).

Like other members of the convertase family, proPC7 undergoes propeptide cleavage within the endoplasmic reticulum (Rousselet *et al.*, 2011). The exact mechanism of

activation is still unknown. PC7 has been shown to undergo many posttranslational modifications such as N-glycosylation and sulfation, modifications which likely confer stability (Seidah *et al.*, 1996). PC7 is the only convertase that is palmitoylated at two cysteines present in the cytosolic domain, a modification which normally affects cellular routing (van de Loo *et al.*, 1997, 2000). Unlike other convertases, the propeptide of PC7 is secreted into the medium (Zhong *et al.*, 1999). Recent studies indicate that the active convertase reaches the cell surface by a conventional, but also by an as yet poorly understood unconventional secretory pathway, while the propeptide traffics through the usual Golgi-dependent route (Rousselet *et al.*, 2011). The transmembrane region of PC7 contains critical and unusual elements which control its intracellular trafficking (Rousselet *et al.*, 2011).

PC7 null mice reveal no apparent abnormal phenotype except loss of anxiety (Besnard *et al.*, 2012); this has been explained by functional redundancy with furin (Seidah, 2011). Interestingly, PC7 colocalizes with brain-derived neurotrophic factor in mouse hippocampus and amygdala; in PC7 null mice, the levels of this neuropeptide are reduced in these brain areas, which affects learning and memory (Wetsel *et al.*, 2013). Among specific functions that differ from furin, PC7 action constitutes a quality control checkpoint in rescuing unstable MHC class I proteins, whereas the related convertase furin is completely dispensable for this process (Leonhardt *et al.*, 2010). PC7 has been implicated in the proteolytic activation of bone morphogenetic protein 4 (BMP4) in *Xenopus* oocytes (Nelsen and Christian, 2009). Lastly, a specific function of PC7, not exhibited by other convertases, is its ability to activate the epidermal growth factor receptor (Rousselet *et al.*, 2011). Much still remains to be learned about this interesting convertase.

Summary and Conclusions

During the past 20 years, we have made considerable progress in elucidating the family members responsible for the regulated proteolysis of signaling molecules. With the exception of PC9, members of the proprotein convertase family of enzymes show relatively similar biochemistry and substrate specificity, which likely accounts for their redundant action in many tissues. Substrate redundancy likely underlies the surprisingly mild phenotype of many knockout mice, for example, those of the endocrine convertases PC1/3 and PC2. While the literature to date indicates that furin is likely involved in hundreds of intracellular basic residue cleavage events, there are many cases where a specific convertase plays the major role in cleaving a certain substrate. It is also possible that redundant convertases are brought into play during specific physiological events. Future studies will undoubtedly identify many more specific convertase substrates. The unique features of each convertase are summarized in Table 2.

The biochemistry of the convertases provides examples of many different kinds of regulated proteolysis. Firstly, the convertases themselves are initially synthesized as inactive forms, and must be activated in the correct subcellular compartment (e.g., the late activation of proPC2 in the mature secretory granules). If PC2 cleaved its substrates prematurely,

Table 2 Expression and special features of proprotein convertases

Enzyme	Tissue distribution	Special features
PC1/3	Neural/endocrine	Slow activity; acidic pH optimum (5.5); operates in TGN and secretory granules; aggregation; and binds proSAAS
PC2	Neural/endocrine	Requires 7B2 to form an activatable precursor; acidic pH optimum (5.0); and operates within secretory granules
Furin	Ubiquitous	Compartment-specific substrate cleavage and transmembrane domain in the C-terminal tail
PC4	Reproductive system	Acrosomal granules (sperm cells) and fertilization
PC5/6	Widespread	Alternative splicing; activation at the cell surface (HSPGs) and transmembrane domain in the C-terminal tail of B forms
PACE4	Widespread	Activation at the cell surface (HSPGs)
PC7	Ubiquitous	Not secreted; Cys-palmitoylation and transmembrane domain in the C-terminal tail

Abbreviations: HSPGs, heparan sulfate proteoglycans; PC, proprotein convertase; TM, transmembrane.

the products would likely not become correctly targeted to the compartment from which they are efficiently released, the secretory granules. Another example is that of the convertase PC5/6, which is maintained as a latent enzymatic activity until the later stages of the secretory pathway, for example, for substrates such as proGdf11 (Sun *et al.*, 2011). A last example of regulated proteolysis is the cell membrane-localized activation of the MMP2 precursor by furin; active MMP2 then acts to cleave the extracellular matrix, a process integral to matrix remodeling as well as to the migration of cancer cells to new locations ('metastasis').

As yet, none of the pharmacological potential of the convertases (other than PC9) has been reached. Challenges for the future include establishing the crystal structures of other convertases aside from furin, and identifying potential therapeutic targets in various diseases. PACE4 is an attractive target for arthritis; furin, and PACE4 can be targeted in cancer; and PC2 can be targeted to inhibit the production of glucagon in diabetes. In the coming years, additional substrates for each enzyme will be identified, and these will likely result in additional pharmacologic targets. As with regulated proteolysis, it may be necessary to restrict therapeutic drug delivery to a specific tissue or time frame in order to achieve a beneficial effect.

PROTEIN SYNTHESIS/DEGRADATION: PROTEIN DEGRADATION – GENERAL

Mass Spectrometry-based Methodologies for Studying Proteolytic Networks and the Degradome

N Solis and CM Overall, University of British Columbia, Vancouver, BC, Canada

Glossary

Degradome The complement of all proteases, their respective substrates and their inhibitors in the proteome.

Degradomics The system-wide study of degradomes employing high-throughput technologies such as chip-arrays, genomics, and proteomics.

Endopeptidase A protease that cleaves at peptide bonds within a protein or peptide rather than at the termini of the protein or peptide.

Exopeptidase A protease that cleaves off the terminal amino acid (or penultimate dipeptide) in a peptide or protein. Aminopeptidases are exopeptidases that act at the N-terminus and carboxypeptidases act at the C-terminus.

Internal N-termini N-termini arising from proteolytic cleavage. Distinct from the original mature N-terminus. Internal N-termini are also known as neo-N termini.

Kinome The complement of all human kinases in the proteome.

LC–MS/MS Liquid chromatography tandem mass spectrometry. The process whereby peptide mixtures are resolved by liquid chromatography (typically reverse phase chromatography) with an ion-pairing agent (e.g., formic acid) that is coupled directly to a mass spectrometer. Eluting peptides are desolvated and ionized into the gas phase directly into a mass spectrometer capable of performing fragmentation. Peptide precursor ions are funneled, selected, and fragmented into fragment ions. Precursor and fragment ions in the mass spectra are used to elucidate the peptide sequence by database searching algorithms.

MS1 quantification Quantification of peptides during LC–MS/MS on the basis of their precursor ion intensities. The intensity of a precursor ion of interest is monitored over its elution profile (retention time) and compared to other peptide ion standards or peptide ion samples. Peptides are labeled with isotopic tags (e.g., dimethylation or SILAC) to enable relative quantification across samples. Fragmentation of the precursor ion yields fragment ions that enable peptide sequence elucidation, thus uncoupling identification and quantification.

MS2 quantification quantification of peptides during LC–MS/MS on the basis of reporter ions following fragmentation of a precursor ion. Peptides in each sample are labeled with different isobaric tags (i.e., the tags have

identical mass). Upon fragmentation (e.g., CID or HCD), these isotopically distinct tags yield a reporter ion unique to that tag. Fragmentation of the precursor ion (MS2) yields fragment ions enabling peptide sequence peptide elucidation and also reporter ions for each chemical tag that allows for relative quantification between samples in one mass spectrum.

MS3 quantification Quantification of peptides during LC–MS/MS on the basis of reporter ions following further fragmentation of a fragment ion. During MS2 quantification, a precursor ion (peptide ion) is selected for fragmentation to yield identification-specific and quantification-specific ions. A second round of fragmentation (MS3) of a fragment ion yields new fragment ions to validate identification of the first fragmentation event as well as reporter ions to provide quantification. MS3 is a feature of ion trap mass spectrometers and provides higher confidence in identification and quantification yet at the cost of sensitivity.

Negative selection of N-termini Enrichment of neo-N-termini by depletion of trypsin/GluC-generated internal peptides. Various strategies are employed to perform negative selection including TAILS and COFRADIC.

Neo N-termini N-termini in proteins or peptides arising from proteolysis; internal N-termini.

Positive selection of N-termini Enrichment of neo-N-termini by affinity purification. The primary amine of each protein N-terminus is tagged with biotin, either enzymatically using an engineered form of subtiligase, or chemically. Digestion with trypsin yields non-modified termini. Biotinylated neo-N-termini are enriched by streptavidin chromatography.

P residues Residues N-terminal to the scissile bond of a protease substrate. If the residue is X residues immediately N-terminal to the scissile bond, it is the PX site (e.g., the P3 site is the third residue N-terminal to the scissile bond of the substrate).

P' residues Residues C-terminal to the scissile bond of a protease substrate. If the residue is X residues immediately C-terminal to the scissile bond, it is the PX' site (e.g., the P3' site is the third residue C-terminal to the scissile bond of the substrate).

Protease web The interdependent network of interactions of all proteases and inhibitors linked by cleavages.

Proteases Enzymes that catalyze the hydrolysis of amide bonds in peptides and proteins. Proteases cleave specific amino acid residues alone or within motifs, the frequency of their occurrence determines how broadly the protease can act on proteins and on proteomes.

Proteome The complement of all proteins and their respective posttranslational modifications in a defined organelle, cell type, tissue, or organism at a particular point in time under defined conditions.

PSP Proteolytic signature peptides. Peptides that can be used to monitor the activation status of a protein. Namely, a fully tryptic unique peptide spanning across a cleavage site for a protease of interest. Detection of the entire tryptic peptide indicates lack of protease activity, whereas detection (and quantification) of the semi-tryptic peptides indicates protease activity for that cleavage site.

SRM Selected reaction monitoring. A form of label-free peptide quantification where the mass spectrometer scans combinations of precursor and then fragment ions, known as transitions, during LC-MS. As well as defined mass/charge (m/z) ratios, transitions designed for known peptides of interest have defined LC retention times and are thus specific to the (unlabeled) peptide of interest. The mass spectrometer scans several transitions during a chromatography experiment and generates an elution profile. Comparison of elution profile areas across samples provides quantification. SRM is non-discovery form of mass spectrometry that is more sensitive than discovery forms.

Subsites The surface sites on a protease into which the residues either side of the scissile bond dock. S subsites receive the P side amino acids lying N-terminal to the cleavage site whereas the S' subsites receive the P' amino acids lying carboxy-terminal to the scissile bond.

TAILS 'Terminal amine isotopic labeling of substrates' is a negative selection technique for the enrichment of protein N-termini. Before trypsin or GluC digestion the primary amine of each protein N-terminus is labeled and blocked with chemical tags that are isotopically coded to enable relative quantification between samples of identical peptides. Proteins are then digested with trypsin (or other proteases, e.g., GluC) and internal tryptic peptides are removed from the sample by binding the reactive primary amines of the newly generated tryptic peptides to a high molecular weight multi-aldehyde-containing polymer (HPG-ALD). Original and neo-N-termini remain in solution and the polymer can be easily removed by ultrafiltration.

Terminome The complement of all protein N-termini (N-terminome) and C-termini (C-terminome) of proteins in a proteome, which includes the mature protein termini and protease generated neo-termini. Terminomes add an additional layer of information of a proteome by providing information on protease dynamics.

Terminomics The study of terminomes employing high-throughput technologies.

Zymogen Inactive protease precursor. Terminal peptide chain must be cleaved or allosterically moved to expose the active site.

Introduction

Proteases were originally considered to be hydrolases with a strict degradative role and not thought to have any particular exciting roles in cellular regulation or development other than the catabolic release of free amino acids required for cellular growth (Freeman *et al.*, 1983). However, the sequencing of multiple eukaryotic genomes other than mice and humans has shown that there is a plethora of proteases throughout the genetic code. Of the 20 126 human genes there are over 560 proteases identified in *Homo sapiens* and 644 in *Mus musculus* (Overall and Blobel, 2007) representing approximately 2.8% of the genes encoded by mammals. In comparison, kinases, a well-described group of regulatory enzymes responsible for attaching phosphate groups to proteins to regulate signal transduction, cellular response to damage, growth, and a myriad of other cellular events, (Hanks *et al.*, 1988) comprise 518 proteins in humans (Manning *et al.*, 2002). The activity of kinases is strictly intracellular or membrane-bound whereas the activity of proteases has been reported intracellularly, extracellularly, on and in cell membranes (Doucet *et al.*, 2008; Lopez-Otin and Overall, 2002; Overall and Blobel, 2007). The protease repertoire in humans is distributed with 273 extracellular proteases, 277 intracellular proteases, and 16 integral membrane proteases (Overall and Blobel, 2007). Due to their

abundance and evolutionary diversity (having different families of proteases on the basis of their sequence and different clans based on structure), proteases possess regulatory roles as varied and critical as those of the human 'kinome.'

Proteases are classified by their molecular mechanism (which is an indirect reflection of their primary structure similarity): in humans, the five classes are aspartate proteases (21 total), cysteine proteases (148 total), metalloproteinases (194 total), serine proteases (175 total), and threonine proteases (28 total) (Overall and Blobel, 2007). Proteases are further distinguished on the basis of their molecular mechanism, namely, endopeptidases and exopeptidases (Barrett and McDonald, 1986). Exopeptidases act by removing the terminal amino acid or the two N-terminal amino acids from an oligopeptide or protein: aminopeptidases cleave an amino acid from the N-terminus (Taylor, 1993) whereas carboxypeptidases remove an amino acid from the C-terminus (Skidgel and Erdos, 2006). In contrast, endopeptidases are able to hydrolyze peptide bonds within a protein or oligopeptide. A protease recognizes a particular stretch of amino acids in its substrate that are accommodated at the binding surface of the protease active site. Upon substrate binding, the protease catalyzes hydrolysis of the peptide bond at the cleavage site. The residues N-terminal to the scissile bond on the substrate are termed the P residues whereas the residues

C-terminal to the scissile bond are termed the P' residues. It is the sequence across P and P' residues that determine protease sequence specificity (Schechter and Berger, 1967). In addition, the protease binding cleft has a similar nomenclature that defines the specificity of the protease: pockets that accommodate P and P' residues of the substrate are termed S subsites and S' subsites respectively (Schechter and Berger, 1967). The interaction between P/P' and S/S' sites is what defines the specificity of the protease: substrate interaction and also influences kinetics of peptide bond hydrolysis.

All proteins are processed by a protease at some point in their life cycle (Doucet et al., 2008). The non-reversible nature of proteolytic cleavage (as opposed to most other post-translational modifications in cells) demands a well-tuned, tightly controlled system for controlling the activation and deactivation of regulatory proteases. Thus proteases are not ubiquitously dispersed in a cell, or even among tissues or time during development and differentiation and are not ubiquitously active: proteases have inhibitors bound to them or exist in inactive forms (zymogens) that are activated upon a defined stimulus.

Controlled proteolytic processing modulates the functions of proteins and thus proteases play multiple crucial roles in cellular regulation. For example, directing proteins to their correct location in the cell by removal of signal sequences (von Heijne, 1990), orchestrating the recruitment of leukocytes during an inflammatory response by processing chemokines (Ajami et al., 2008; Dean et al., 2008; McQuibban et al., 2002), processing cytoplasmic proteins involved in cell cycle regulation (e.g., processing of cyclins; King et al., 1996), zymogen activation (activation of other proteases; Neurath and Walsh, 1976; Wiederanders et al., 2003), quality control (proteasome-mediated degradation; Ciechanover, 2005) as well as extracellular matrix remodeling (by matrix metalloproteinases and other proteases). Hence it is no surprise that proteases represent 5–10% of all drug targets (Overall and Blobel, 2007).

Perhaps one of the most important concepts to arise in recent years is that proteases act in concerted networks, termed the protease web, to transmit and amplify signals (Fortelny et al., 2014) – somewhat analogous to a kinase pathway. Protease cascades *in vivo* are dynamic and well regulated. For example, the proteolytic processing cascades of coagulation (Hoffman and Monroe, 2007) and caspases (Pop and Salvesen, 2009) allow for signal amplification and many points of regulation that culminate in the formation of a fibrin clot or apoptosis, respectively. In both cases, a carefully concerted action of proteases and other proteins is tightly regulated to prevent untimely clot formation or cell death. Moreover, once a signal has initiated and the appropriate response been effected, the cascade must be 'switched off.' Switching off a protease is typically achieved by biological inhibitors – molecules that can bind the active site of a protease to prevent it from binding substrate; or binding an allosteric site (remote region from the binding site) that alters the conformation of the protease, thus preventing it from binding substrate (Turk et al., 2012). For instance, in the coagulation cascade, in order to prevent further thrombin clot production, the serine protease inhibitor (serpin) antithrombin inactivates thrombin (Seegers et al., 1954) and activated protein C cleaves FVa and FVIIIa (Hoffman and Monroe, 2007).

Although in the examples of coagulation and apoptosis there is a wealth of information regarding the key proteases, of the approximately 600 proteases in humans, 50% have no known substrates (Fortelny et al., 2014) and no known regulatory functions or *in vivo* functionalities (Doucet et al., 2008). Moreover, not all substrates of a particular protease that are determined *in vitro* or bioinformatically are relevant *in vivo*. Proteases, their respective substrates and inhibitors do not always coexist in the same cellular compartment, do not exist in the concentrations typically used in *in vitro* assays, are not always in complexes required for function (such as the proteasome), or do not have substrates folded in the correct conformation. As such, despite the power of *in vitro* assays to determine substrates and protease cleavage sites, these lack the depth, throughput and *in vivo* relevance given by animal models or cell lines that display proteases in action. Consequently, in order to study the complete set of proteases, their respective substrates, spatio-temporal expression profiles and phenotypic effects (defined as the 'degradome') the field of 'degradomics' has emerged.

Degradomics

The convergence of several technologies over the past two decades including high-throughput genome sequencing (genomics), ionization methods for biological molecules in mass spectrometry (Fenn et al., 1989; Karas et al., 1985), microarray (chip) technology (Lopez-Otin and Overall, 2002), increased computational power and reliable high pressure liquid chromatography (HPLC) systems has resulted in the birth of proteomics (Washburn et al., 2001). Proteomics is the systematic characterization of all proteins and peptides and their posttranslational modifications at a particular time in a cell or tissue. Developments in this rapidly advancing field have allowed unprecedented sensitivity, throughput, robustness and relative ease in not only the systematic identification of thousands of proteins and peptides from complex biological samples but also the relative (and absolute) quantitation of such molecular species. Degradomics utilizes techniques spanning many disciplines of biochemistry such as protease substrates, cleavage specificities, substrate chips, protease-activity chips, DNA microarray chips, or protease-specific protein chips and these have been extensively described elsewhere (Lopez-Otin and Overall, 2002).

Due to the high level of success of proteomic approaches employed in degradomics we will discuss some strategies to identify and quantify the cleavage specificities of unknown proteases, the substrates of a particular protease and validation techniques that could be employed to independently prove the results obtained from high-throughput technologies.

Identification of Protease Substrates

Substrates define protease function. The identification of cleaved proteins from the neo-N-termini in a sample after treatment of that sample with a protease or in a biological model expressing a mutant (inactive) form of the protease or not expressing it at all (knockout model) compared with a

control sample (showing regular proteolytic processing patterns) can yield information on the substrates that are targeted by that protease and hence their *in vivo* roles. All biological samples contain background proteolysis products. Therefore effective unbiased methods of substrate discovery must be employed that can efficiently discriminate between basal proteolysis and the protease-specific cleavage products with high confidence. Thus methods need to be employed that are capable of 'subtracting' background products in a control sample from the induced proteolysis products. Therefore, for this aim quantitative proteomics approaches need to be employed over non-quantitative approaches where one sample can be compared to another under the same conditions in order to subtract the background cleavage products, for example, control versus protease-containing. The following section describes experimental procedures for global approaches to identify substrates and we will not dwell upon techniques that do not provide this essential feature.

Classical gel-based methods

Theoretically, a protein that has been processed by a protease will have a lower mass and potentially a different isoelectric point (pI – the pH when a protein has no net charge) indicating a shift in the ratio of charged amino acids. Such an event can be easily visualized utilizing two-dimensional gel electrophoresis (2-DE). During this process, proteins are denatured, cysteine residues are blocked to prevent disulfide bond reformation by reduction and alkylation, and are separated according to charge on a low percentage acrylamide strip using isoelectric focusing (IEF). The strip is then embedded in a gradient acrylamide gel and proteins are resolved

by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) according to their mass. Following staining of the gel, a map of all proteins (as individual protein spots) resolved on the basis of both charge and mass is obtained, allowing for visual identification of differences in spot patterns (Gorg *et al.*, 2004). Protein in each spot can be extracted, digested with a site-specific enzyme (most commonly trypsin) and the resulting peptide fragments identified utilizing mass spectrometry (MS) – commonly known as peptide mass fingerprinting (PMF) (Figure 1; Pappin *et al.*, 1993). However, 2-DE alone is not quantitative, suffers from reproducibility problems and only allows for the profiling of proteins which are highly abundant and soluble in gel-compatible buffers.

Quantitative differences between samples using 2-DE can be achieved using fluorescently labeled dyes (Cy dyes), referred to as differential in gel electrophoresis (DIGE) (Unlu *et al.*, 1997). The samples to be compared are labeled with different Cy dyes and can also be compared to an internal standard. Different samples are electrophoresed on the same gel, which eliminates gel-to-gel variation as well as providing relative quantitation not only for all intact proteins but also their modified cleaved variants by visualizing the gel under the different wavelengths used to excite the fluorescent labels (Figure 1). Despite these advantages, however, DIGE often does not resolve cleavages near the N- or C-termini, does not identify the cleavage site, is labor intensive, low throughput, and requires scanners capable of excitation at several wavelengths.

While 2-DE and DIGE have relied on protein identification mainly by PMF and also suffered from dynamic range issues an alternative gel-based strategy was developed by the Cravatt

Figure 1 Differential in gel electrophoresis (DIGE). (a) (1) Two samples, one exhibiting more protease processing (shown in black) processing than the other; (2) Each is treated with a separate Cy dye (red and green in the figure); (3) Proteins are resolved by charge and mass using two-dimensional gel electrophoresis. Note that the wild-type protein (red) is of higher mass and different charge than the processed protein (green). Scanning at different wavelengths will show proteins with different Cy dyes which correspond to different samples. (b) (1) Protein of interest is extracted from the gel; (2) Protein extract is digested with a site-specific protease (e.g., trypsin); (3) MS analysis of peptide fragments derived from the protein of interest will result in peptide masses to be searched against a database yielding the identification of the protein. In addition to mass spectrometric analysis, proteins that have been excised in gel-based approaches can also have N-terminal peptides identified by Edman degradation. Edman sequencing can only target peptides with non-modified N-terminal residues as the first step is the reaction of phenylisothiocyanate with the amino group from N termini under alkaline conditions. This reaction cyclizes the N-terminus which then under heat and acidic conditions releases the N-terminal residue in the form of a phenylthiohydantoin amino acid derivative. This derivative can be identified by chromatography or electrophoresis and iteration of this many times yields the sequence of the target peptide (Edman *et al.*, 1950).

Figure 2 Liquid chromatography tandem mass spectrometry (LC-MS/MS). (a) Proteins are extracted and purified for analysis; (b) Proteins are digested with a site-specific protease (e.g., trypsin); (c) Peptide fragments are purified and resolved by reversed phase-HPLC coupled directly to ionization (e.g., ESI); (d) Ions enter the mass spectrometer where they are scanned in MS1. An ion selected for fragmentation (indicated by a red square in the MS1 spectrum) is fragmented and the fragment ions are scanned in MS2; (e) Fragmentation patterns are saved to lists which are searched with programs such as Mascot, Andromeda, and X! Tandem; (f) Protein identifications can be inferred from peptide sequences.

laboratory termed 'Protein Topography and Migration Analysis Platform – PROTOMAP' (Dix *et al.*, 2008). This is essentially identical to the 1-D gel-based substrate identification approach of Guo *et al.* (2002), but without isotopic labeling as used by Guo *et al.* (2002). Dix *et al.* utilize and distribute accessible software analysis to render the approach more amenable for widespread adoption. Guo's 1-D approach and PROTOMAP are conceptually distinct from the 2D gel-based methods. Each sample (e.g., control and test) is solubilized and electrophoresed on separate lanes of a 1-D SDS-PAGE gel. Each lane is then sliced into equal lengths and trypsinized in gel. Peptides from each lane slice can then be analyzed by liquid chromatography tandem mass spectrometry (LC-MS/MS) in order to identify the proteins in each gel band. LC-MS/MS consists of peptide separation by chromatography coupled directly to an ionization source (commonly electrospray ionization, ESI) and mass analysis in the mass spectrometer using one or various fragmentation techniques (Figure 2). In Guo's 1-D approach the proteins and cleaved fragments are manually determined. In PROTOMAP examination of protein identifications, spectral counts (the number of times a peptide ion was fragmented) and most importantly, sequence coverage, generates profiles for each protein – termed peptographs (Dix *et al.*, 2014). Guo's 1-D gel and PROTOMAP can yield semi-quantitative information on hundreds of proteins in a single analysis due to the high throughput of LC-MS/MS in comparison to PMF (Washburn *et al.*, 2001).

The effectiveness of PROTOMAP was initially demonstrated in the analysis of apoptosis-mediated protease substrates in a Jurkat T cell model (Dix *et al.*, 2008) and showed significant power over previous gel-based methodologies (PROTOMAP identified 260 proteins being cleaved during apoptosis while previous gel-based methods identified 49 (Brockstedt *et al.*, 1998; Gerner *et al.*, 2000; Thiede *et al.*, 2006; Thiede *et al.*, 2005). Furthermore, PROTOMAP circumvents

the need for Cy dyes (thus cheaper, and does not necessitate advanced equipment and imaging software), is technically easy, has a higher dynamic range than other 2D gel-based methods and provides full-length protein information and topology. However, despite the advantages and power of PROTOMAP, it was not originally intended to determine cleavage sites which can be easily missed still and it can suffer from poor resolution. Cleavage fragments near the termini are often not resolved. Nevertheless, PROTOMAP remains an inexpensive, effective and powerful method and has been extensively applied, for example, in the examination of proteolysis during malaria infection (Bowyer *et al.*, 2011), biomarker discovery in cancer (Shen *et al.*, 2012), and coagulation (Niessen *et al.*, 2011).

Gel-free methods (mass spectrometry-based)

Identification of protein fragments by gel-free methods is a non-trivial problem and still remains a technical challenge in proteomics in general, and not just degradomics, due to the high complexity and high dynamic range (i.e., highly abundant proteins obscuring low abundance ones) of biological samples being processed for MS analysis. Often a single protease-specific cleavage site must be identified amongst hundreds to thousands of proteins in the proteome in order to identify pathway involvement and develop biological knowledge. The sample is further complicated since prior to mass spectrometry the proteins in the sample need to be digested to smaller sizes to be amenable to MS. Peptides are easily handled, have well-defined chromatographic characteristics, and are amenable to MS, allowing accurate measurement on the basis of mass-to-charge ratio (m/z) (Abersold and Mann, 2003). Complex peptide mixtures are frequently fractionated by liquid column chromatography prior to MS. Furthermore, by colliding peptide ions inside the mass spectrometer (either using a variety of fragmentation methods including

collision-induced dissociation (CID) (Wells and McLuckey, 2005), higher collisional dissociation (HCD) (Olsen *et al.*, 2007), and electron transfer dissociation (ETD) (Syka *et al.*, 2004)) sequence-specific ions can be generated and used for sequence elucidation by means of database searching algorithms (e.g., Sequest, Eng *et al.*, 1994; Mascot, Perkins *et al.*, 1999; X! Tandem, Craig and Beavis, 2003 and Andromeda, Cox *et al.*, 2011). The availability of completely sequenced whole genomes has provided a rich source of information that has enabled proteomic technologies to be high-throughput. This is due to the ability to search MS/MS spectra against protein databases of the most commonly used organisms in a short period of time.

In order to identify one or a few protease cleavage sites in a whole proteome, it is imperative to simplify the sample and to enrich for the relevant neo-N or neo-C terminal peptides. Separating peptides using several different chromatographic chemistries, high speed and high resolution mass spectrometers and comprehensive computer algorithms coupled to powerful computing nodes now routinely yields peptide sequence identifications in the tens of thousands – orders of magnitude higher than gel-based methods or Edman sequencing reactions (Edman *et al.*, 1950).

In addition to ‘identification’ of peptide sequences, relative ‘quantification’ of peptides (or absolute quantification if standards with known concentration are spiked into the sample; Fahlman *et al.*, 2014) between control, protease-treated or even among different test conditions of samples can be confidently obtained using chemical labeling strategies (Ross *et al.*, 2004; Thompson *et al.*, 2003).

Quantitation can be performed in three modes: MS1 quantification (Egertson *et al.*, 2013) where quantitative information is obtained in the primary scan (MS1 scan) in the

mass spectrometer after labeling by dimethylation or SILAC and the peptide sequence can be determined from a subsequent fragmentation event of the quantified ion; MS2 quantification carried out in the tandem MS scan (MS2 scan, containing all fragment ion signals used for peptide sequence inference) (e.g., iTRAQ tags (isobaric tags for relative and absolute quantification; Ross *et al.*, 2004)) or TMT tags (tandem mass tags; Thompson *et al.*, 2003; Figure 2), and recently MS3 quantification which is performed on reporter ions generated during fragmentation of fragment ions (that is, a further iteration of quantification using MS2 methods with iTRAQ and TMT). During MS1-based quantification, quantification is provided without the need for peptide fragmentation as the tags have different masses which the mass spectrometer can resolve; the fragmentation is necessitated solely for identification. In contrast, MS2-based quantification requires fragmentation for simultaneous quantification and identification as the tags have the same mass (isobaric) and their reporter regions have different masses that are used in MS2 analysis. An additional round of fragmentation on product ions can yield more confident quantification results (due to lack of interfering peptide ions in a close mass range) in MS3 quantification. So that identical peptides with different isobaric tags fly together in MS1 mode the different tags must add up to the same mass. Therefore, balance groups within each tag are included so that the fragmented balance component of the tag has a different mass and importantly the labeled peptide displays a tag with a different mass for each of the 4, 6, 8, or recently 10 tags (Figure 3). Terminal amine isotopic labeling of substrates (TAILS), described below, can be utilized with either MS1, MS2, or MS3 quantitation techniques depending on the isotopic label, but for the purposes of illustration only isotopically labeled dimethyl tags (MS1 quantification) will be

Figure 3 MS2 quantification scheme using 4-plex iTRAQ tags. (a) Schematic representation of isobaric iTRAQ tags. Each tag has a reporter ion group (114 through 117 Da), a peptide-reactive group (indicated by a star) and a balance group (31 through 28 Da). The balance group ensures that all tags add up to 145 Da. (b) (1) Each sample (here a single peptide indicated by a wavy line) is labeled with a different iTRAQ tag (reporter groups indicated by different colors and kept in separate tubes); (2) Individual labeled samples are then be combined prior to LC-MS/MS; (3) All iTRAQ tags have identical chromatographic properties allowing mixing of samples and co-elution during LC-MS/MS; (4) For a population of the same peptide labeled with different iTRAQ tags, a single peptide ion is detected during MS1 and selected for fragmentation; (5) The selected peptide ion is fragmented yielding reporter ions (highlighted in gray) and peptide sequence ions (highlighted in purple) in the MS2 scan. Relative intensities of reporter ions provides quantitative information while peptide sequence ions provides identification information; (6) Further selection and fragmentation of peptide fragment ions from the MS2 scan can yield refined reporter ions for higher accuracy quantitation (MS3 quantification).

discussed. Subtiligase biotinylation to date has not employed quantification by isotopic labeling whereas Combined Fractional Diagonal Chromatography (COFRADIC) has mainly utilized MS1 quantification.

Relative quantification using dimethylation

For relative quantification of peptides between samples, for instance a test sample with over-expressed or deleted protease of interest compared to a control sample only displaying background levels of proteolytic processing, samples are each treated with a different formaldehyde tag that reacts with primary amines of free N-termini (α -amine groups) and lysine side chains (ϵ -amine groups). These tags are chemically identical to each other – thus displaying identical chromatographic properties, equal signal in MS intensity as well as linearity in response to quantity (i.e., truly quantitative chemical labels). The only difference between the tags used for each sample are the number of neutrons – namely, the ‘light’ version of the tag is CH_2O , the ‘medium’ tag being CD_2O (D being deuterium) and the ‘heavy’ form of the tag being $^{13}\text{CD}_2\text{O}$. Hence, there is a difference of 4 Da between tags, giving each peptide in the samples a unique identifier – the intensity of each ion providing relative quantitation between samples (Boersema *et al.*, 2009) while fragmentation of the peptide ion yields product ions that provide the information for the identification of the peptide sequence.

Negative Selection of N-termini by Combined Fractional Diagonal Chromatography (COFRADIC)

The earliest methods for isolating peptides that originate from proteolytic events in a cell (native peptides) is COFRADIC (Gevaert *et al.*, 2002). COFRADIC was first used to isolate methionine-containing peptides from the model organism *Escherichia coli*. Over 800 proteins were identified from 5×10^7 cells and COFRADIC was estimated to be 100 times more sensitive than the previously described gel-based methodologies (Gevaert *et al.*, 2002). COFRADIC exploits two key physical principles that peptides display during chromatographic separation. Firstly, peptides will elute consistently at the same retention time during chromatographic separation between analytical runs if identical parameters (flow rate, buffer compositions, column dimensions, etc.) are used; and secondly, chemical modification of a peptide will result in an altered interaction with the solid-phase of the chromatographic column that manifests as a shift in retention time.

To identify peptides that have originated during protease processing in the cell, proteins are isolated and acetylated to block all free amine groups on N-termini and lysine side chains, rendering them unreactive. Proteins are then digested with trypsin that generates a variety of reactive free internal N-termini and separated by reverse phase (RP) HPLC into several fractions – with each peptide eluting after a particular retention time. Each fraction is treated with 2,4,6-trinitrobenzenesulfonic acid

Figure 4 Combined fractional diagonal chromatography (COFRADIC). (a) Proteins have their amines blocked (e.g., by acetylation); (b) Proteins are digested with a site-specific protease (e.g., trypsin or GluC) generating a variety of internal N-termini; (c) Peptides are separated by HPLC; (d) Considered here peptides at 17 min retention time; (e) Peptide fraction is treated with TNBS; (f) Peptide fraction is again resolved using identical HPLC, however due to TNBS treatment, internal N-termini display a strong hydrophobic shift. Native peptide still elutes at 17 min but internal N-terminus elutes much later and can be discarded.

(TNBS) which reacts selectively with the free α -amino groups (namely, all internal N-termini resulting from tryptic digestion) and each fraction is then run again on RP-HPLC using identical conditions as the primary run. Neo-N-termini from proteins in the original sample were blocked (acetylated) and so will elute at the same time as in the primary run and can easily be collected. However, peptides derived from tryptic digestion are TNBS-modified and consequently display a strong hydrophobic shift (increased retention time) and can now be discarded (Figure 4; Gevaert *et al.*, 2003). Thereby, neo-N-termini have been refined from the total peptide pool and can be identified by LC-MS/MS. COFRADIC enables the separation not only of mature protein and neo-N-terminal peptides but of any desired modification provided that the reaction step between the primary and secondary runs are specific for this modification – making COFRADIC an extremely versatile and effective targeted technique for sampling the proteome with exquisite resolution that can be automated. The main caveats lie principally in the need for multiple chromatographic steps, which demand technical reproducibility, large sample amounts to account for potential losses at each step, but perhaps above all, the extensive chromatography time required to obtain such samples for one experiment followed by many MS analyses to analyze all the sample fractions, even > 100. Despite this, COFRADIC remains an attractive and versatile method to target the degradome and other post-translational modifications.

Negative selection of N-terminal peptides by Terminal Amine Isotopic Labeling of Substrates (TAILS)

A more recent simplified N-terminomics procedure termed TAILS (Kleifeld *et al.*, 2010, 2011; Doucet *et al.*, 2011) has the advantage of starting with as little as 200 μ g protein per channel followed by 1–3 MS analyses only. Amino groups comprising the α amines of N-termini of mature protein and cleaved neo-N-termini of proteins in the sample and of lysine side chains are chemically protected at the whole protein level.

This is the key as it is simple to discriminate any N-terminus of native proteins that were present in the sample before trypsinization from internal N-terminal peptides arising after tryptic digestion during proteomic processing. Chemical blocking of α - and ϵ -amine groups (i.e., those present on the N-terminus and lysines respectively) with different isotopes, renders them unreactive as well as providing each sample with a unique mass tag that allows quantitation during MS analyses.

Following amine blocking (e.g., dimethylation with CH_2O , CD_2O , or $^{13}\text{CD}_2\text{O}$, or MS2 tags like iTRAQ and TMTs) protein samples are combined and digested with trypsin to yield free internal N-termini that are reactive. For negative selection, the peptide mixture is reacted with a commercially available highly branched polymer containing 1000s of aldehyde groups (HPG-ALD, see Relevant Websites), which captures free reactive N-termini under reductive conditions, while all peptides that do not have a free amino group (i.e., protease substrate neo-N-termini and natural N-termini blocked by dimethylation in TAILS or naturally blocked by acetylation or pyroglutamate formation) will not bind and therefore remain free in solution. The polymer and bound peptides are then removed by ultrafiltration, and the blocked peptides can be collected for LC-MS/MS analysis (Kleifeld *et al.*, 2010; Figure 5). The product is a highly simplified mixture of peptides that enables easier identification and quantitation by LC-MS/MS, yet as with all methodologies there are caveats and advantages. This method offers a technically much simpler protocol than COFRADIC, as well as a statistical platform for data analysis of the identifications when using MS2 quantification (CLIPPER) (auf dem Keller *et al.*, 2010), all reagents are commercially available, and the process can be multiplexed for simultaneous analyses of several samples. Additionally, the reaction of internal tryptic peptide N-termini with HPG-ALD is efficient, rapid, and demonstrates minimal non-specific peptide binding. TAILS has been widely adopted by many companies and laboratories now by virtue of its rapid processing and ease of preparation, minimal mass spectrometry time

Figure 5 Terminal Amine Isotopic Labeling of Substrates (TAILS). (a) Consider three protein samples. Each sample is treated with a different dimethyl label (light, medium and heavy – each differing in mass by 4 Da). Each sample has all amine groups blocked; (b) Samples are combined and digested with a site-specific protease (e.g., trypsin); (c) Internal N-termini bind aldehyde groups in the HPG-ALD polymer, retaining all neo-N-termini in solution; (d) HPG-ALD containing all internal N-termini peptides are removed by ultrafiltration and neo-N-termini are identified and quantified by LC-MS/MS as observed by a difference of 4 Da between peptide ions corresponding to a single native N-terminus.

required for analysis with the advantage of also identifying the N-termini of mature proteins which can be used for statistical modeling and data normalization, comprehensive analysis of the entire N-terminome, as well as for identifying N-terminal peptide cleavage sites.

TAILS also has variation of the approach for the isolation of C-terminal peptides (C-TAILS) that although effective at targeting the C-terminome still cannot achieve similar number of identifications as N-TAILS (Schilling *et al.*, 2010). However, with no alternative C-terminal enrichment methods available, C-TAILS remains the method of choice with the caveat of having lower peptide identifications than for N-TAILS.

In vivo analyses are confounded by a number of different variables that makes the identification and quantification of neo-N-termini challenging regardless of the methodology employed. Not only do *in vivo* analyses suffer from biological variability between animals or tissues but the variability in quantification of protease substrates is also attributed to other factors: Tissues are responsive biological systems that upon stimulus will alter their transcriptional regulation and hence protein synthesis, vascular permeability (which alters the plasma protein composition in pathologically affected tissues), and cell migration (e.g., the infiltration of neutrophils and macrophages upon inflammation or infection (McQuibban *et al.*, 2002)). Thus, an influx of proteins from either serum entering at higher amounts due to increased blood flow and vessel permeability, or turnover products from effector cells acting at the site of stimulus can increase the amount of particular proteins that would lead to a perceived increase of protease activity on the basis of increased amount of neo-N-termini pertaining to that protein. An example of overcoming these issues was demonstrated in the examination of proteolytic events of complement activation during skin inflammation (auf dem Keller *et al.*, 2013). The authors used a murine model of skin inflammation matrix metalloproteinase 2 (MMP2)-deficient mice and utilized N-TAILS with MS2 quantification (iTRAQ-TAILS) to elucidate protease substrates *in vivo*. A very effective way to truly unravel if the protease substrates quantified are truly a biological signature in response to a stimulus is to normalize the results obtained in the N-terminome analysis to whole protein ratios. Analysis of natural N-termini ratios provides information if there is altered protein synthesis or import from plasma or infiltrating cells. TAILS offers a way to examine the changes in proteome abundance by examining the relative ratios of peptides prior to HPG-ALD depletion (preTAILS). Since proteins are labeled with iTRAQ reagent, the peptides remain labeled (on N-termini and lysine residues) following tryptic digestion which permits direct LC-MS/MS analysis that complements TAILS (preTAILS and TAILS analyses). Comparisons of preTAILS relative ratios across native N-termini and proteins to substrates identified by TAILS provided the normalization (protein context) required to infer true protease signatures during skin inflammation (auf dem Keller *et al.*, 2013).

Positive Selection of N-Terminal Peptides by Subtiligase Biotinylation

Neo-N-termini can be labeled with a biotin tag that is cleavable by means of the highly site-specific TEV (tobacco etch

virus) protease. In this case, the ϵ -amino group of lysine residues are not protected as N-terminal specific biotinylation is performed by subtiligase (Mahrus *et al.*, 2008), a genetically-engineered enzyme that exclusively attaches an engineered biotin tag (a biotin moiety linked to the TEV cleavage site) to the N-terminus of available proteins and peptides. Proteins are digested with trypsin (to allow for database identification following LC-MS/MS) and the entire peptide samples are passed through a streptavidin column washing out all trypsin-generated internal N-termini. Peptides are cleaved from the biotin tag by TEV protease, exclusively at the TEV cleavage site linking the biotin tag and native peptide. As a consequence of such processing, all TEV processed native peptides will initiate with the dipeptide sequence Ser-Tyr which can also serve as diagnostic ions during the fragmentation event in LC-MS/MS, thus providing a simple yet effective manner of validating peptide identifications by positive selection of native termini (Mahrus *et al.*, 2008; Figure 6).

Positive enrichment of subtiligase biotinylated neo-N-termini offers a number of advantages over COFRADIC: enrichment is relatively simple and the chromatographic separation is faster and requires less instrumentation than in COFRADIC, allowing for higher throughput as well as diagnostic ion confirmation in the case of the subtiligase method. However, limitations with positive enrichment include false-positive binding events in the streptavidin affinity step (an issue circumvented entirely by COFRADIC), a requirement for relatively large sample amounts (50–100 mg) due to lower efficiencies in labeling, loss of natural N-termini that are not captured if they are N-terminally blocked, for example, acetylated, so these peptides cannot be used for data normalization, N-terminomics analyses or substrate discovery (if cut within the N-terminal peptide leading to low peptide ratios due to cleavage versus the intact N-terminal peptide of the control sample), and perhaps a troublesome issue is that subtiligase is a patent-protected enzyme – making it less appealing than easily commercially available alternatives. However, COFRADIC and subtiligase-directed biotinylation are potentially compatible with isotope labeling, although only reported using MS1 quantification for COFRADIC, allowing quantification by mass spectrometry and thus providing information on protease cleavage events and protein abundance across different tissues/conditions.

Identification of Protease Cleavage Motifs

Proteomic identification of protease cleavage site specificity

The availability of complete genome sequences, largely due to high-throughput sequencing projects, now offers a rich source of information that can be exploited to profile the specificities of proteases. An entire tryptic digested proteome was conceived as an extensive peptide library offering a plethora of biologically relevant amino acid combinations that will most likely contain cleavage sequences specific to a protease. This is the basis for proteomic identification of protease 'cleavage site specificity (PICS)' (Schilling and Overall, 2008; Schilling *et al.*, 2011) and although other methods exist to profile cleavage specificities of proteases (such as phage display libraries;

Figure 6 Enzymatic biotinylation. (a) Proteome is treated with subtiligase, which exclusively biotinylates N termini; (b) Protein sample is digested with a site-specific protease as trypsin or GluC; (c) Streptavidin affinity capture retains biotinylated neo-N-termini as native N-termini pass through the column; (d) Biotinylated peptides are released by TEV protease cleavage and collected for LC-MS/MS (the orange circle denotes the leader dipeptide Ser-Tyr characteristic after TEV protease cleavage of the biotin reagent); (e) Signature pair of ions (Ser-Tyr) can be used as diagnostic positive controls during MS analysis. Here the orange head corresponds to Ser-Tyr and the fragment ions corresponding to Ser-Tyr are highlighted orange whereas sequence-specific ions are highlighted gray.

Matthews and Wells, 1993), we will only discuss PICS as a gel-free proteomics technique as it alone has the advantage of profiling both the prime and non-prime sites simultaneously in the same analysis.

To perform a PICS experiment, an entire proteome (typically the human proteome, as it offers a larger list of proteins compared to microorganisms or less complex eukaryotes) is digested with a site-specific protease (usually trypsin and GluC are used to make separate libraries. Both trypsin and GluC are utilized to maximize coverage of the libraries in complementary fashion. Namely, the cleavage site specificity for trypsin is C-terminal to arginines and lysines whereas for GluC it is C-terminal to glutamic acid. Thus, tryptic peptide libraries contain internal Asp and Glu residues, GluC libraries contain internal Lys and Arg residues) and all amine groups are blocked (rendering them unreactive to the subsequent biotinylation steps). Such a complex peptide mixture can act as a library with the potential to contain sequences that are cleaved by the test protease. The test protease is allowed to proteolytically process the peptide library yielding a variety of unblocked neo-N-termini on the prime side of the cleavage site, which are positively selected using a chemical biotinylation strategy using NHS-biotinylation. Biotinylated peptides can then be isolated following disulfide bond reduction and identified by LC-MS/MS (Schilling and Overall, 2008).

Information obtained through LC-MS/MS yields the peptide sequence with the N-terminus of the neo-N-terminal peptide being the prime side of the cleavage site (P' site), which can then be mapped back to the genome to determine the non-prime side, P sites N-terminal to the scissile bond. Assembling hundreds of the cleavage sites enables one to infer a consensus substrate motif (Figure 7). Thus, PICS offers a rapid, inexpensive and relatively simple approach to confidently identify protease consensus cleavage sites from up to thousands of cleavage events by using readily available and established proteomic technologies and software.

Validation of Degradomic Data

Perhaps as important as having high confidence proteomic data (both in terms of identification and quantification of substrates) is to provide insight into biological processes by validation of these data. Validation experiments by biological assays which address hypotheses generated by large-scale proteomic experiments convert possible biological information into actual biological information. This is a particularly important distinction as all large-scale data is subject to large biological variability that can be statistically difficult to analyze in terms of relatively low numbers of biological

Figure 7 Proteomic identification of protease cleavage site specificity (PICS). (a) A proteome sample is digested to peptides by trypsin and then has all amines blocked; (b) the test protease is allowed to cleave the proteome derived peptide library resulting in neo-N-termini at the cleavage site; (c) neo-N-termini are chemically biotinylated; (d) utilizing a streptavidin capture column, all tryptic peptides are washed while only retaining those caused by the protease treatment; (e) biotinylated peptides are eluted and then identified by LC-MS/MS. Following bioinformatic analysis a consensus motif can be constructed on available proteomic data and genome sequences.

samples that can be processed per proteomic approach as well as the inherent technical variations in all MS-based technologies. In other words, by using complementary techniques, biological knowledge can be obtained by converting moderately quantitative information on several substrates (degradomic profiling) into highly quantitative (and phenotypic) information on few substrates.

There have been numerous publications now utilizing methods such as COFRADIC and TAILS in both *in vitro* models (e.g., Becker-Pauly *et al.*, 2011; Holmberg *et al.*, 2013; Papadioti *et al.*, 2012; Starr *et al.*, 2012; Wejda *et al.*, 2012) as well as *in vivo* analyses in human and murine models (auf dem Keller *et al.*, 2013; Jefferson *et al.*, 2011; Lange *et al.*, 2014; Lewandrowski *et al.*, 2009; Marchant *et al.*, 2014). Identification of protease substrates by mass spectrometry requires a combination of manual annotation and validation of individual mass spectra but also validation by usage of different database searching algorithms and post-processing tools (Keller *et al.*, 2002; Nesvizhskii *et al.*, 2003). These data can be confirmed by *in vitro* assays to validate cleavage. However, the consistent confirmation of cleavage sites identified by mass spectrometry with confirmatory Edman degradation has now nearly eliminated the need for *in vitro* validation of cleavage sites. This signifies that mass spectrometric data needs to be validated in terms of protease activity, and phenotypic characteristics in the model being investigated.

Why is validation of accurate mass spectrometric data one aspect for inferring protease biology? Proteases are subject to

many different stimuli that can affect their conformation, specificity, subcellular localization, activation and inhibition which all contribute to their overall activity. The use of a particular biological model, be it *in vitro* or *in vivo*, comes with advantages and disadvantages that can make the interpretation of degradomic data challenging. For instance, overexpression of a protease in tissues not normally expressing the protease will generate a situation of high protease:substrate thus resulting in an artificially high number of substrates being identified that might never occur *in vivo*. Overexpression in tissues not normally expressing the protease also would lead to substrates being cleaved that are not normally encountered by the active protease. Thus, overexpression studies have considerably less power than analysis of knockout animals.

Additionally, there is biological redundancy – that is, proteases from the same enzyme family may compensate for the induced loss of a particular protease (Fortelny *et al.*, 2014). Some of these questions may not be exclusively addressed using the proteomic data alone but can be using alternate verification methods such as selected reaction monitoring (SRM). SRMs are a label-free method for quantifying selected peptides across several samples using LC-MS/MS; and more importantly the use of a variety of cell lines and animal models that can be integrated into biological assays testing overlapping proteomic data sets to confirm hypotheses. Further to SRMs, validation of protease activity at a particular cleavage site can be performed utilizing proteolytic signature peptides (PSP). A unique tryptic peptide spanning a cleavage

site in a protein can be monitored by SRM or MS2 labeling as an indicator of activation of the protease recognizing that cleavage site motif. If the protease is active, the tryptic peptide will not be present. Rather, two semi-tryptic peptides will be present (their termini being at the cleavage site). Normalization across a protein can be achieved by also monitoring peptides on the same protein that do not cover the cleavage site motif ('Standard of expressed protein', STEP) thus accounting for protein abundance. Because synthetic standard peptide mixtures (PSP and STEP) are spiked into the sample for quantification analysis, not only relative quantification can be obtained, but also, absolute quantification over a large dynamic range and low limit of quantification (Fahlman *et al.*, 2014). This provides a relatively simple, powerful, and targeted method to monitor protease activities circumventing issues encountered by activity-based probe technologies and has been recently used to profile MMP2 activation and activity *in vivo* (Fahlman *et al.*, 2014).

There are several tools for the *in vivo* analysis of proteases that typically involve mouse models due to their relative ease of manipulation and high biological similarity that can be extrapolated for further human research. The scope of this chapter is not to examine all of these tools, but they have been reviewed extensively elsewhere (Overall and Blobel, 2007). For testing the global effects of a protease, knocking-out the protease or knocking-in an inactive protease (inserting a mutation in the active site rendering the protease inactive) may be employed to observe the phenotypic effects *in vivo* and also correlate to substrates identified by proteomic experiments as these two functionally similar methods address different questions. Namely, if the protease exists in a complex, the biological effect will likely be different if that protease is removed entirely (knockout) or simply inactivated in the complex (catalytic-site-inactivating knock-in)? In an analogous fashion, upon identification of a particular protease substrate associated with a phenotype, strategies include knocking-in the substrate with a modified protease cleavage site making it resistant to the tested protease, or knocking-out the substrate (Overall and Blobel, 2007).

Conclusions

The ability to globally profile different aspects of protease biology utilizing MS-based methods has produced a revolution in how protease function is viewed today. Proteases are compartmentalized to prevent substrate processing, they exist in complexes and trigger many signals (both proteolytic and non-proteolytic, Turk *et al.*, 2012), that result in modified phenotypes, such as the coagulation cascade (Hoffman and Monroe, 2007) or apoptosis (Elmore, 2007). Novel techniques to analyze proteolytic processing and the increasing amount of information regarding proteases being stored and made publicly available (for example, MEROPS, Rawlings *et al.*, 2012 and TopFIND databases, Lange and Overall, 2011, 2013; Lange *et al.*, 2012), has shown that proteases exist in networks, originally proposed and termed the protease web (Dean and Overall, 2007) and validated recently as a highly pervasive interdependent network of interactions (Fortelny *et al.*, 2014). Proteases are dynamic and their activities not only affect their direct substrates but in turn the entire system

to which they are connected that can dictate the balance between a signal being activated or remaining in homeostasis (Overall and Blobel, 2007; Turk *et al.*, 2012).

In addition, increasing power in technologies not only associated with MS but also cell lines, animal models, microscopy, *etc.*, have also opened a new frontier to validate these systems-wide studies and have begun to reveal the exquisite regulation these webs have and their potential as targets for drugs and novel therapeutics. Protease research is still exploring new avenues of biological regulation and the development and refinement of degradomic techniques is critical to answer questions such as interplay in the protease web, does proteolytic signaling affect kinase signaling or vice-versa, how do complexes interact once a particular proteolytic signal has targeted it, *etc.* One recent example of novel biological regulation mediated by proteases is the case of MMP12 during viral infection in a murine model (Marchant *et al.*, 2014). MMP12^{-/-} knockout animals challenged with coxsackievirus display significant morbidity and are unable to mount an effective immune response. Utilizing a combination of TAILS and chromatin immunopurification-sequencing (ChIPSEQ) MMP12 was shown to act not only as an extracellular protease, but also an intracellular protease and strikingly, as a transcription factor. ChIPSEQ analysis (which allows for the identification of transcriptionally regulated genes) revealed that MMP12 directly binds DNA and represses several genes. Furthermore, using TAILS it was found that 177 substrates were processed by MMP12 that also were transcriptionally regulated by MMP12, *i.e.*, these are dual regulated substrates by MMP12. Combination of various genomic, proteomic *in vitro* and *in vivo* models, degradomics is now flourishing into an integrated field that is now allowing for the examination of new frontiers in protease biology.

General Background

Intracellular protein degradation is a highly selective and regulated process as indicated by the fact that different proteins have different half-lives. Moreover, the half-life of a protein can vary in response to internal or external cues allowing, for example, the correct execution of spatio-temporally regulated processes (e.g., cell cycle, cell differentiation, and signal transduction pathways). Besides its manifold functions in controlling/regulating particular pathways or processes, protein degradation also plays a pivotal role in more general processes such as protein quality control (removal of 'abnormal', e.g., misfolded or misassembled proteins), amino acid homeostasis (e.g., under starvation conditions), and immune surveillance (generation of peptides presented at the cellular surface by major histocompatibility complexes). To ensure that proteins are not randomly destroyed – which would be deleterious for a cell – but are degraded only when appropriate, eukaryotes have evolved two complex systems for selective degradation of intracellular proteins, the autophagic-lysosomal system and the ubiquitin-proteasome system (UPS).

Ubiquitin and Ubiquitin-like Proteins

Introductory Comments

A critical issue in selective protein degradation is how a protease discriminates between proteins that should be degraded and those that should not be targeted. In principle, this can be achieved by two, non-mutually exclusive mechanisms: proteins contain a defined amino acid sequence and structure that serve as a recognition and degradation signal, or proteins are flagged for degradation by a distinct posttranslational

modification. The first mechanism is mainly followed by site-specific proteases and results in protein processing rather than complete degradation; the substrate spectrum of such proteases is limited. In contrast, the second mechanism allows the specific recognition and degradation of many different proteins by a single protease, and this mechanism has been adopted by the UPS: proteins are first modified by covalent attachment of ubiquitin ('ubiquitylation' or 'ubiquitination'), which serves as recognition signal for a multi-subunit protease complex, the 26S proteasome.

Ubiquitin

Ubiquitin was discovered in 1975 (Goldstein *et al.*, 1975) and two years later, it was shown that a certain fraction of histone 2A (H2A) is covalently modified by a single moiety of ubiquitin via isopeptide bond formation between the carboxyl group of the C-terminal glycine of ubiquitin and the ϵ -amino group of a defined lysine residue of H2A (Goldknopf and Busch, 1977; Hunt and Dayhoff, 1977). This was the first description of protein–protein modification but it took almost 30 years to uncover the function(s) of histone ubiquitylation (Weake and Workman, 2008). In the late 1970s/early 1980s, biochemical characterization of a eukaryotic non-lysosomal ATP-dependent proteolytic system revealed that its substrates are ubiquitylated prior to recognition and degradation by a protease complex, which later on was identified as the 26S proteasome (Etlinger and Goldberg, 1977; Ciechanover *et al.*, 1978, 1980; Wilkinson *et al.*, 1980; Hershko and Ciechanover, 1998). In addition, evidence was provided that proteolytic substrates are modified by a ubiquitin chain or ubiquitin polymer consisting of several ubiquitin moieties connected by isopeptide bonds rather than by a single moiety of ubiquitin (Hershko *et al.*, 1980; Chau *et al.*, 1989).

Figure 1 Conjugation of ubiquitin and ubiquitin-like proteins. (a) Structures of ubiquitin (PDB 1UBQ), SUMO (PDB 1A5R), and SAMP (PDB 3P00). (b) The ubiquitin conjugation cascade. Ubiquitin is activated by an E1 activating enzyme by forming a thioester bond between the C-terminal glycine of ubiquitin and the catalytic cysteine residue of E1 at the expense of ATP. Activated ubiquitin is then transferred to an E2 conjugating enzyme in a transesterification reaction. Finally, E2s in concert with E3 ubiquitin-protein ligases, which mediate substrate recognition, catalyze the covalent attachment of ubiquitin to a substrate protein via isopeptide bond formation. Based on their functional properties, E3s can be classified into three groups. In case of HECT E3s and RBR E3s, activated ubiquitin is transferred from the E2 to the E3 in a transesterification reaction and isopeptide bond formation is catalyzed by the E3 itself, while RING E3s act as adaptors between substrates and E2s, and at least in some cases act as allosteric activators of E2s. Depending on the type of ubiquitylation, proteins are targeted for degradation by the 26S proteasome (e.g., modification by K48-linked ubiquitin chains) or for non-proteolytic fates (e.g., monoubiquitylation, modification by K63-linked ubiquitin chains). Finally, it should be noted that ubiquitylation is a reversible process by the action of deubiquitylating enzymes (DUBs) (not shown) and that modification of proteins by ubiquitin-like proteins is catalyzed by enzymatic cascades similar to the ubiquitin-conjugation system. For further details, see main text. (c) Ubiquitylation involves two types of covalent protein-protein interactions: thioester complexes between the carboxyl group of the C-terminal glycine of ubiquitin and the catalytic cysteine residue of E1, E2s, and HECT and RBR E3s; (iso)peptide bonds between the carboxyl group of the C-terminal glycine of ubiquitin and the ϵ -amino group of lysine residues or the α -amino group of the N-terminal residue of a substrate.

Ubiquitin is a 76 amino acid polypeptide that is highly conserved among eukaryotes and adopts a compact globular fold, the β -grasp or ubiquitin-like fold (Vijay-Kumar *et al.*, 1987; Burroughs *et al.*, 2012; Figure 1). *Saccharomyces cerevisiae* and humans contain four genes encoding ‘pro-ubiquitin’ – head-to-tail-fusions of several ubiquitin moieties or ubiquitin fused to ribosomal subunits (Wiborg *et al.*, 1985; Ozkaynak *et al.*, 1987; Baker and Board, 1987). Free ubiquitin is generated from such fusion proteins by deubiquitylating enzymes (DUBs) (Komander *et al.*, 2009; Reyes-Turcu *et al.*, 2009). Covalent attachment of ubiquitin to target proteins is mediated by an elaborate enzymatic conjugation cascade (see below); in most cases, lysine residues serve as acceptors for ubiquitin but in some cases, ubiquitin can also be attached to the α -amino group of the N-terminal residue of a protein or to

serine or threonine residues via the formation of a peptide bond or ester bond, respectively. In addition to ‘mono-ubiquitylation’ (attachment of a single ubiquitin to a lysine residue) and multiple mono-ubiquitylation (several lysine residues of a substrate are modified by single ubiquitin moieties), ubiquitin can serve as its own substrate resulting in the formation of ubiquitin chains on target proteins (‘poly-ubiquitylation’). Ubiquitin contains seven lysine residues (K6, 11, 27, 29, 33, 48, 63) and each of these as well as its N-terminal residue can serve as an attachment site for ubiquitin resulting in 8 homotypic (the same lysine is used for ubiquitin attachment throughout the chain), numerous heterotypic chains (different lysines used within one chain), and branched chains (two or more lysines of one ubiquitin are ubiquitylated) (Komander and Rape, 2012).

The diversity of ubiquitylation or 'ubiquitin signals' indicates that different types of these fulfill different functions. Indeed, different ubiquitin chains adopt different topologies, and K48-linked and K11-linked ubiquitin chains mainly represent signals for proteasomal degradation, while K63-linked chains fulfill non-proteasomal functions. Similarly, mono-ubiquitylation is mainly a signal for non-proteasomal fates (e.g., endocytosis) but in some cases may also target proteins for proteasomal degradation (Komander and Rape, 2012; Kravtsova-Ivantsiv and Ciechanover, 2012; Kravtsova-Ivantsiv *et al.*, 2013). In a simplistic view, attachment of ubiquitin or ubiquitin chains alters the biochemical properties of a modified protein. This can be achieved by inducing a conformational change (e.g., allosteric activation or inhibition of enzymatic activities) or by creating or shielding a protein-protein interaction surface. In many cases, decoding the different ubiquitin signals involves proteins with ubiquitin-binding domains that recognize the ubiquitin-like fold or in some cases the specific ubiquitin chain type (e.g., K48-linked or linear chains). Different ubiquitin-binding domains can be grouped into distinct families based on structural similarities (Dikic *et al.*, 2009; Husnjak and Dikic, 2012); however, it remains to be determined if structural similarities are correlated strictly to functional similarities.

The ubiquitin-like fold consists of a four-stranded anti-parallel β -sheet with an α -helix on top of the β -sheet (Figure 1). This fold is not only found in eukaryotic proteins but also in prokaryotic ones including ThiS and MoaD that are not covalently attached to other proteins but serve as sulfur carriers in biosynthetic pathways (see below) (Hochstrasser, 2009; Burroughs *et al.*, 2012). In this context, it should be noted that the concept of earmarking proteins for degradation by protein-protein modification is also used by some eubacteria but the respective modifying protein (e.g., prokaryotic ubiquitin-like protein, Pup) does not show any structural similarity to

ubiquitin (see below, Pearce *et al.*, 2008). The small archaeal modifier proteins (SAMP) found in some archaea, in contrast, share the β -grasp fold with ubiquitin (e.g. Humbard and Maupin-Furlow, 2013). There are nearly 20 human proteins that share primary sequence and structural similarity with ubiquitin and are covalently conjugated to proteins or other molecules (note that ubiquitin-like domains are also found as part of eukaryotic proteins that cannot be covalently attached to other proteins (Hochstrasser, 2000)). Some of the more thoroughly characterized ubiquitin-like proteins (UBLs), described further below, include small ubiquitin-like modifier (SUMO) family members, neural precursor cell expressed developmentally downregulated-8 (Nedd8), IFN-stimulated gene, 15 kDa (ISG15), and two UBLs involved in autophagy, Atg8 and Atg15 (Table 1). A discussion of these UBLs highlights some commonalities and differences in the organization of their conjugation and deconjugation systems, as well as the remarkable functional divergence of these protein modifiers. The functions of other UBLs are just beginning to be understood, and in some cases are revealing the evolutionary origins of all eukaryotic UBLs (Hochstrasser, 2009; Burroughs *et al.*, 2012).

Ubiquitin-Conjugation System

Ubiquitin is conjugated to substrate proteins by the concerted action of three classes of enzymes: In the first step, ubiquitin is put into a chemically reactive state by a ubiquitin-activating enzyme (E1, UBA, UBE1) at the expense of ATP. The activated ubiquitin is then transferred from E1 to a ubiquitin-conjugating enzyme (E2, UBC, UBE2). Finally, the E2 in conjunction with a ubiquitin-protein ligase (E3, UBE3), which mediates substrate recognition, transfers ubiquitin to a substrate protein by isopeptide bond formation. This general scheme of conjugation (Figure 1) as well as the underlying biochemical mechanisms have been elucidated in the 1980s

Table 1 The enzymes (E1s, E2s, E3s, and Deconjugation Enzymes), targets, and functions for some of the most thoroughly characterized ubiquitin-like proteins (UBLs)

UBL	E1	E2	E3(s)	Deconjugating enzyme(s)	Targets	Function(s)
SUMO1-4	SAE1/UBA2 heterodimer	UBE2I (UBC9)	SIZ/PIAS proteins, RanBP2	SENP family proteases	Numerous, generally containing ψ KxD/E motif	Numerous, including localization, and recognition signal for STUBs
NEDD8	APPBP1/UBA3 heterodimer	UBE2M (UBC12)	RBX1, RBX2 DENN1	CSN complex (CSN5 catalytic subunit)	Cullin proteins	Activation of Cullin-containing ubiquitin ligases
ISG15	UBA7 (UBE1L)	UBE2L6 (UBCH8)	HERC5	USP 18 (and several virus-encoded DUBs)	Newly synthesized proteins	Innate immunity
LC3 proteins (ATG8)	ATG7	ATG3	ATG12-ATG5-ATG16 complex	ATG4	Phosphatidylethanolamine	Autophagy; phagophore membrane formation, cargo recruitment
ATG12	ATG7	ATG10	N/A	N/A	ATG5	Component of the ATG12-ATG5-ATG16 ligase for LC3 proteins

(Ciechanover *et al.*, 1982; Haas *et al.*, 1982; Hershko *et al.*, 1983; Hershko and Ciechanover, 1998) and apply also to the conjugation of UBLs (see below). The hierarchical mode of ubiquitin conjugation is reflected in the number of the respective enzymes, with one (*S. cerevisiae*) or two (human) E1 enzymes, 11 (*S. cerevisiae*) or approximately 30 (human) E2s, and several hundred E3s.

The ubiquitin E1 enzyme is a monomer with three functional entities: an adenylation domain, a domain containing the catalytically active cysteine residue, and a ubiquitin fold domain (UFD). The adenylation domain contains an ATP-binding site and catalyzes the formation of a ubiquitin (acyl)-adenylate. The acyl-adenylate is then nucleophilically attacked by the thiol group of the active site cysteine residue resulting in the formation of a thioester complex between E1 and ubiquitin. The UFD as well as part of the catalytic cysteine-containing domain provide binding sites for E2 enzymes (Hanzelmann *et al.*, 2012). The essential role of the ubiquitin-conjugation system *in vivo* and its involvement in the cell division cycle and protein quality control became clear through the identification and characterization of a mouse cell line (ts85) bearing a temperature-sensitive E1 (Finley *et al.*, 1984; Ciechanover *et al.*, 1984).

E2 enzymes are characterized by the presence of the catalytic ubiquitin-conjugating (UBC) domain of approx. 150 amino acids in length. Some E2s consist just of this domain indicating that the UBC domain unites the four main properties of E2s: association with E1 as well as with E3 enzymes, formation of ubiquitin-thioester complexes, and covalent attachment of ubiquitin to target proteins by isopeptide bond formation (Hanzelmann *et al.*, 2012). In a simplified model, upon binding to the E1 UFD, the catalytic site cysteine of the E2 becomes located in close proximity to the catalytic cysteine of E1. This results in transfer of ubiquitin from E1 to the catalytic cysteine residue of E2 in a trans-thioesterification reaction followed by release of the ubiquitin-loaded E2. This change in affinity ('high' affinity of free E2 for ubiquitin-loaded E1, 'low' affinity of ubiquitin-loaded E2 for E1) is required to allow the ubiquitin-loaded E2 to interact with its cognate E3(s), since the binding surfaces of E2 for E1 and E3s overlap (and, thus, binding of the two is mutually exclusive). From the E2, ubiquitin is then transferred either to a target protein, which in most cases occurs in conjunction with an E3, or to an E3 in a trans-thioesterification reaction (Figure 1).

Some E2s have, in addition to the UBC domain, N-terminal and C-terminal extensions. The diversity in composition/structure contributes to the functional specialization of E2s. In general, a given E2 interacts only with a distinct subset of E3s (e.g., UBC6 and UBC7 interact with E3s involved in endoplasmic reticulum-associated degradation (ERAD), UbcH10 is one of the cognate E2s of the anaphase promoting complex (APC)/cyclosome (Smith *et al.*, 2011; Meyer and Rape, 2011)) and may be found at distinct intracellular localizations (e.g., UBC6 is an integral ER membrane protein). Furthermore, besides their involvement in the control of different cellular processes, different E2s may catalyze the formation of different types of ubiquitin chains (e.g., the Mms2-Ubc13 complex forms K63-linked ubiquitin chains, UbcH10 and Ubc6 form K11-linked chains (Hanzelmann *et al.*, 2012; Meyer and Rape, 2011; Xu *et al.*, 2009)).

For the integrity of a cell, ubiquitylation has to be a highly specific and, at least in some cases, regulated process. The need for specificity is reflected by the number of E3s: the human genome encodes several hundred putative E3s, with each E3 presumably having a distinct and limited substrate spectrum. Based on functional considerations, E3s can be categorized into three groups: HECT (homologous to E6AP C terminus) E3s, RING (really interesting new gene) and RING-like (U box) E3s, and RBR (Ring-in-between-RING) E3s (Berndsen and Wolberger, 2014). HECT E3s were the first family of E3s described (Huibregtse *et al.*, 1995). They are characterized by the presence of a C-terminal HECT domain of approximately 350 amino acids in length. The HECT domain mediates the interaction with cognate E2 enzymes, contains the catalytic cysteine residue, which accepts ubiquitin from the E2 in a trans-thioesterification reaction, and catalyzes the covalent attachment of ubiquitin to substrate proteins. The human genome encodes 28 HECT proteins ranging in size from approximately 80–600 kDa. HECT proteins can be categorized into three subfamilies based on the presence of known protein–protein interaction motifs in their respective N-terminal extensions, which presumably define the substrate spectrum of HECT E3s. Furthermore, some HECT E3s preferentially build up K63-linked ubiquitin chains (e.g., yeast Rsp5), while others form K48-linked ubiquitin chains (e.g., E6AP) thereby targeting proteins for proteasomal degradation (Scheffner and Kumar, 2014).

RING E3s are the largest known E3 family with the human genome encoding approximately 500 RING domain-containing proteins (Metzger *et al.*, 2014). The RING domain consists of approximately 40–60 amino acids and comprises 6 or 7 cysteine residues and 2 or 1 histidine residues that coordinate 2 Zn^{2+} ions in a so-called cross-braced manner. The RING domain mediates the interaction with cognate E2s and at least in some cases acts as an allosteric activator of E2s (i.e., in contrast to HECT E3s, ubiquitin is transferred directly from the E2 to the substrate; Figure 1). Based on their composition, RING E3s can be roughly grouped into E3s in which the substrate recognition domain and the RING domain are located on the same polypeptide (note that such RING E3s frequently function in the form of homo-dimers or hetero-dimers; e.g., Mdm2, Mdm2-MdmX, BRCA1-BARD1), and multi-subunit E3s, in which substrate recognition is mediated by a protein other than the RING domain protein. Examples for the latter are the Cullin-RING ligases (CRLs), including SCF complexes consisting of CUL1, RBX1 (RING protein), SKP1, and an exchangeable F-box protein, which mediates substrate recognition, and CBC complexes consisting of CUL2 or CUL5, RBX1 or RBX2, Elongins B and C, and as substrate recognition components VHL-box or SOCS-box proteins (Zimmerman *et al.*, 2010; Lydeard *et al.*, 2013; Deshaies and Joazeiro, 2009). Another prominent example is the APC/cyclosome, which consists of at least 13 subunits with APC11 being a RING domain protein and CDH1 and CDC20 being substrate recognition components (Bassermann *et al.*, 2014). Since the human genome encodes approximately 90 F-box substrate adaptor proteins (the F-box represents the interaction site for SKP1, while substrate recognition is mediated by other regions that differ between different F-box proteins), the combinatorial nature of multi-subunit E3s enlarges the substrate spectrum of the ubiquitin-conjugation system.

The catalytic domain of RBR E3s consists of two RING domains (RING1, RING2) that are linked by an in-between RING domain. RING1 serves as interaction site for ubiquitin-loaded E2s, while RING2 contains a catalytic cysteine residue that accepts ubiquitin from E2 in a trans-thioesterification reaction and presumably catalyzes the covalent attachment of ubiquitin to substrate proteins (Wenzel and Klevit, 2012; Smit and Sixma, 2014). Thus, RBR E3s follow a RING/HECT hybrid-like mechanism of ubiquitylation. Prominent members of this E3 family (the human genome encodes 14 RBR E3s) are PARKIN and the HOIL–HOIP complex, which catalyzes the formation of N-terminally linked ('linear') ubiquitin chains on substrate proteins.

Although it remains to be determined if all HECT/RING/RBR domain-containing proteins indeed function as E3s, the sheer number of putative E3s indicates that the ubiquitin-conjugation system has the potential to target any protein in a cell in a highly specific manner (note that most, if not all, intracellular proteins are ubiquitylated at some stage during their lifetime; e.g., Kim *et al.*, 2011). Indeed, substrates of the ubiquitin-conjugation system are not characterized by a unifying amino acid sequence or region which serves as common recognition signal. Rather each E3 recognizes a distinct subset of sequence motifs that depends on the protein–protein interaction motifs the E3 contains (e.g., substrates of the APC/cyclosome often contain a so-called KEN box, while substrates of the NEDD4 subfamily of HECT E3s frequently display PPxY motifs (Barford, 2011; Scheffner and Kumar, 2014)). Furthermore, some proteins are targeted for degradation only at certain times during the cell cycle, development or differentiation or in response to distinct extracellular stimuli. This temporal regulation can be achieved at the level of E3 or substrate. For example, cofactors are in some cases required to activate a given E3 (e.g., Smad7-mediated activation of Smurf2 (Scheffner and Kumar, 2014)) or substrates of SCF complexes need to be phosphorylated before they are recognized by their cognate F-box proteins (Deshaies and Joazeiro, 2009). In fact, in many cases, there is a crosstalk between components of the ubiquitin-conjugation system and other posttranslational modification systems that ensures appropriate ubiquitylation and degradation of a given protein (see also below, sections 'SUMO' and 'NEDD8'). Thus, the actual mechanisms involved in regulating ubiquitylation of a given protein need to be determined for each individual substrate-E3 pair.

DUBs

Ubiquitylation is a dynamic process inasmuch as it can be reversed by the action of DUBs. The human genome encodes approximately 90 different DUBs that can be grouped into 5 families: ubiquitin C-terminal hydrolases (UCHs), ubiquitin-specific proteases (USPs), ovarian tumor domain (OTU) proteases, Josephin domain proteases (MJD), and Jab1/MPN/Mov34 (JAMM) metalloproteases (Komander *et al.*, 2009; Reyes-Turcu *et al.*, 2009; Clague *et al.*, 2012; Eletre and Wilkinson, 2014). While the first four are members of the cysteine protease superfamily, the latter are Zn-dependent enzymes. Besides their role as antagonists of E2/E3 enzymes (i.e. by removing ubiquitin from substrate proteins), DUBs are

required for processing pro-ubiquitin molecules (see section 'Ubiquitin') into mature ubiquitin monomers and for regenerating mono-ubiquitin from ubiquitin chains liberated from polyubiquitylated proteins by other DUBs, for example at the proteasome, or from free ubiquitin chains that may serve as reservoir for mono-ubiquitin in cells.

The balance between ubiquitylation and deubiquitylation eventually decides whether a protein is degraded or not, indicating that the activities of DUBs must be tightly controlled. Similar to other proteases, DUBs show little activity unless they are associated with cognate substrates or scaffolding proteins, presumably ensuring that 'non-substrates' are not coincidentally cleaved (Liz and Sousa, 2005). Furthermore, DUBs in general do not just consist of the catalytic domain but have additional domains such as ubiquitin binding domains and protein-protein interaction motifs. While the former are involved in determining the type of ubiquitin chain a DUB may recognize (Komander *et al.*, 2009; Reyes-Turcu *et al.*, 2009; Clague *et al.*, 2012; Eletre and Wilkinson, 2014), the latter may define the subcellular localization of a DUB or may affect its activity. For example, three DUBs have been associated with the 26S proteasome (POH1, UCH37, USP14) with POH1 (the human ortholog of yeast Rpn11) and UCH37 being integral components of the 19S regulatory particle (19S RP; see below). Furthermore, the yeast ortholog of USP14, Ubp6, interacts with the E3 ligase Hul5. This is thought to fine-tune the length of ubiquitin chains attached to substrates of Hul5 (Crosas *et al.*, 2006). Finally, DUB activity is subjected to regulation at the level of expression and at the posttranslational level by phosphorylation/dephosphorylation, ubiquitylation, and sumoylation (Komander *et al.*, 2009; Reyes-Turcu *et al.*, 2009; Clague *et al.*, 2012; Eletre and Wilkinson, 2014).

SUMO Family Members

SUMO is found in all eukaryotes, with four related SUMO proteins in most vertebrates (SUMO1-4). SUMO2 and 3 are nearly identical and about 50% identical to SUMO1 (Gareau and Lima, 2010). SUMO4 is most similar to SUMO2, although it remains unclear whether it is actually conjugated to other proteins. SUMO2/3 and yeast SUMO can form poly-SUMO chains, while SUMO1 does not. A single heterodimeric E1 activating enzyme (AOS1/UBA2) and a single E2 protein (Ubc9) mediate all SUMO conjugation. Unusual for UBLs, most SUMOylated proteins have a consensus modification site, consisting of ψ -K-x-D/E (where ψ is a bulky hydrophobic residue, x is any amino acid, and K is the actual modification site), and Ubc9 can generally directly recognize this modification site, at least *in vitro*. Variations on the consensus motif exist, as well, including phosphorylation-dependent recognition sites. E3s for SUMO are few in number, but include RanBP2 and the SIZ/PIAS family of proteins. The problem of how specific substrate recognition is established, and the mechanisms of SUMO E3s, remains an active area of investigation. There are several SUMO isopeptidases, including six human sentrin-specific protease (SENP) proteins, which have varying specificities for SUMO paralogs and types of SUMO linkages. As with ubiquitin, the balance between SUMOylation

and deSUMOylation is likely a key to the regulation of the biological functions of SUMO.

SUMO interacting motifs (SIMs) play a central part in mediating the biologic functions of SUMOylation. Particularly interesting examples of SIM-containing proteins are the STUBs (SUMO-targeted ubiquitin ligases), which are E3 ubiquitin ligases that ubiquitylate SUMOylated proteins (Perry *et al.*, 2008; Geoffroy and Hay, 2009; Sriramachandran and Dohmen, 2014). In this setting, SUMOylation serves as a posttranslational modification that triggers ubiquitylation through binding of the SUMOylated protein to the SIM of the STUB. SIMs also exist in some SUMO E3s (e.g., RanBP2 and Siz/PIAS proteins), aiding in the recruitment and orientation of Ubc9~SUMO complexes.

The substrates of SUMOylation are numerous and diverse (Xu and Peng, 2006). Although substrate proteins are found in many locales, proteins associated with the nucleus are particularly abundant. A wide range of transcriptional regulators, chromatin modifiers, nucleolar substrates, and centromeric and telomeric substrates have been identified (Jentsch and Psakhye, 2013; Cubenas-Potts and Matunis, 2013; Nagai *et al.*, 2011). The range of effects of SUMOylation can include changes in protein stability, protein localization, assembly of multi-protein structures, and alteration of enzyme activity. In short, it is not possible to define a single biochemical function for SUMOylation. This is certainly due, in part, to the nature of the conjugates (the specific SUMO paralog, whether a protein is poly-SUMOylated) and the interplay of SUMOylation with other types of protein modifications (e.g., ubiquitylation and protein acetylation).

NEDD8

NEDD8 is a key regulator of Cullin-Ring ubiquitin ligases (CRLs) (Sarikas *et al.*, 2011). CRLs play critical roles in a diverse array of essential cellular processes, including cell cycle regulation and signaling pathways. The E1 enzyme for NEDD8 is NAE, and the major E2 enzyme is Ubc12 (Ube2M). Like the SUMO E1, NAE is a heterodimer of proteins (APP-BP1/Uba3) that, together, structurally and functionally resemble the monomeric E1 enzyme for ubiquitin. Cullin proteins form the 'scaffold' around which the multi-subunit CRLs are built, with a RING domain protein associated at one end of the rigid cullin, and adaptor proteins and substrate binding proteins associated at the other. A RING domain protein, RBX1 or RBX2, functions to recruit ubiquitin E2 proteins; however, it binds to unmodified cullins in a conformation that restrains the RING domain from interacting with E2 proteins. The NEDDylation of the cullin at a single conserved lysine residue near the RBX binding site alters the conformation of RBX1/2, freeing the RING domain to interact productively with ubiquitin E2 proteins (Lydeard *et al.*, 2013).

Cullin proteins (seven in humans) constitute the predominant targets of NEDDylation. The de-NEDDylation of Cullins is tightly controlled by the COP9 signalosome complex, which contains a metalloproteinase subunit, COP9 signalosome subunit 5 (CSN5), with de-NEDDylase activity (Deshaies *et al.*, 2010). While there is still much to be sorted out with respect to regulation, and not all cullins may be

subject to the same regulation, it appears that de-NEDDylated cullins preferentially associate with CAND1; and CAND1 drives dissociation of what is normally a very stable association of the Cullin with its substrate adaptors. Therefore, while NEDDylation activates the ligase function of CRLs, de-NEDDylation constitutes part of a cycle that allows a limited number of Cullin proteins to dynamically associate with a wide array of substrate recruitment proteins, accounting for the tremendous variety of CRL target proteins. Consistent with the role of CRLs in regulating many cancer-related signaling pathways, a specific NAE inhibitor (MLN4924) is currently in clinical trials as a cancer therapeutic (Nawrocki *et al.*, 2012).

ISG15

ISG15 is a vertebrate-specific UBL that consists of two ubiquitin-like domains connected by a short flexible linker. The most striking feature of ISG15 is that it is strongly induced at the transcriptional level by type 1 interferon (IFN- α/β) signaling, implying a role for ISG15 conjugation in the innate immune response. The E1, E2, and predominant E3 enzymes for ISG15 are Ube11 (UBA7), UbcH8 (UBE2L6), and Herc5, respectively, and like ISG15, the genes encoding these enzymes are induced by IFN- α/β signaling (Durfee and Huibregtse, 2012). Mouse Ubp43 and its human ortholog Usp18 are interferon-induced deconjugation enzymes for ISG15 (Malakhov *et al.*, 2002). Several hundred cellular proteins have been identified as ISG15 targets in IFN-stimulated cells, although no clear pattern with respect to function or intracellular localization emerged from these analyses. A remarkable aspect of this conjugation pathway is that Herc5 mediates conjugation to the vast majority of these proteins. The basis of this broad recognition is that Herc5 is stably associated with the 60S ribosome, allowing Herc5 to conjugate ISG15 to nearly any protein that is being translated in the cell. Thus, it was proposed that ISGylation of newly synthesized proteins is essentially a stochastic process, and that, in the context of a virus-induced interferon response, newly synthesized viral proteins (rather than cellular proteins) may be the biologically relevant targets of ISG15 (Durfee *et al.*, 2010). ISG15 does not appear to target proteins for degradation or form poly-ISG15 chains. The basis of its antiviral activity may simply be that it serves to disrupt the function of viral proteins to which it is conjugated. The range of viruses that have been shown to be sensitive to the anti-viral effects of ISG15 include Influenza viruses, Herpesviruses, HIV, and Chikungunyavirus (Morales and Lenschow, 2013). Interestingly, several viruses have evolved mechanisms to either prevent ISG15 conjugation or reverse ISGylation via virus-encoded DUB-like proteins (Zhao *et al.*, 2013).

Early studies reported that ISG15 was a secreted cytokine that induced IFN- γ production (D'Cunha *et al.*, 1996). This surprising result is consistent with the recent identification of human patients harboring homozygous loss-of-function mutations in the ISG15 gene (Bogunovic *et al.*, 2012). These patients developed significant mycobacterial disease after receiving a live attenuated mycobacterial vaccine. IFN- γ signaling is critical for the response to mycobacterial infection, and further experiments confirmed that extracellular ISG15 induces IFN- γ production from peripheral blood mononuclear cells

(PBMcs). Thus, ISG15 appears to have two very different functions – one as an intracellular posttranslational modifier, and one as an extracellular cytokine-like molecule. The mode of secretion and cytokine-like signaling remain unknown.

ATG8/LC3 and ATG12: Key Players in Autophagy

Autophagy is a mechanism that eukaryotic cells use for bulk degradation of cytoplasmic organelles and other constituents (Hurley and Schulman, 2014). It is characterized by the phagophore, a double-membrane structure that engulfs cytoplasmic material (the autophagosome), which then fuses with the lysosome, delivering its contents for degradation. This process is triggered by nutrient starvation and other stresses and provides a source of building blocks for biosynthesis and energy production. Among the many proteins that participate in coordinating and regulating this cellular reorganization are two UBLs, ATG8/LC3 and ATG12 (Klionsky and Schulman, 2014). ATG8 (yeast) and LC3 (mammalian cells) are unusual in that they are not conjugated to a protein, but rather to the amine group of a lipid, phosphatidylethanolamine (PE). This complex then becomes part of the phagophore membrane and plays a role in regulating the expansion of the membrane. There are six LC3-related proteins in human cells that may have distinct functions in regulating the phagophore membrane. The β -grasp domain of the conjugate also interacts with and recruits other proteins, including cargo, to the autophagosome (Slobodkin and Elazar, 2013).

The second UBL in the autophagy pathway, ATG12, actually forms part of the ligase that is involved in conjugating ATG8/LC3 to PE (Hanada *et al.*, 2007). ATG12 is conjugated to another autophagy protein, ATG5, and the ATG12-ATG5 complex binds to ATG16. The ATG12-ATG5-ATG16 complex then acts as an E3 ligase for ATG8, covalently attaching it to PE. Other ATG proteins are involved in upstream steps in this process. ATG7 is the E1-like enzyme for both ATG8/LC3 and ATG12. ATG7 then transfers ATG8/LC3 to an E2-like protein, ATG3, and ATG12 to another E2-like protein, ATG10. From ATG10, ATG12 is passed to ATG5. ATG4 is a protease that processes ATG8 at its C terminus prior to its conjugation and can liberate the ATG8/LC3 from its PE conjugates. This amazing system illustrates the diversity of uses of UBLs. Much remains to be discovered regarding the function and regulation of ATG8 conjugation and deconjugation to phagophore lipids and the biophysical effects of this on membrane dynamics (Klionsky and Schulman, 2014).

Other UBLs

While the examples above illustrate the diversity of functions of UBLs, there are several others that promise to reveal other interesting aspects of cellular regulation. FAT10 is a vertebrate-specific UBL that, like ISG15, is a translational dimer of ubiquitin-like domains (Schmidtke *et al.*, 2014). FAT10 expression is induced by IFN- γ and TNF- α , primarily in tissues of the immune system. While its precise biologic role is unclear, like ubiquitin, it appears to target proteins for proteasomal recognition. URM1 is a UBL that is unusual in that it is involved in sulfur transfer reactions for thionucleoside

(e.g., 2-thiouridine) modification of tRNAs (Shigi, 2014). A URM1 thiocarboxylate is an intermediate in this reaction. This certainly reflects the early evolutionary origins of UBL systems, as sulfur transfer reactions in molybdopterin and thiamin biosynthesis in bacteria employ β -grasp proteins with terminal di-Glycine signatures (MoaD and ThiS) to transfer thiol groups to intermediates in their respective biosynthetic pathways (Hochstrasser, 2009; Burroughs *et al.*, 2012). Further, these bacterial UBLs are activated by E1-like enzymes, MoeB and ThiF, that are clearly structurally and mechanistically related to the E1 proteins of all UBLs.

The 26S Proteasome

Introductory Comments

The 26S proteasome is a macromolecular protease and central player in the UPS of eukaryotic cells. It mediates the degradation of proteins tagged with certain types of ubiquitin chains (Finley, 2009; Tomko and Hochstrasser, 2013). Some proteins, however, are also degraded in a ubiquitin-independent manner (Erales and Coffino, 2014). More simple evolutionary relatives of eukaryotic proteasomes are found in various archaeons and in one group of eubacteria (Actinomycetales) (Humbard and Maupin-Furrow, 2013). These prokaryotic proteasomes share the principle architecture with the catalytic core particle (CP) of eukaryotic proteasomes, which is also known as the 20S proteasome (Baumeister *et al.*, 1998). The 26S proteasome is composed of a 20S CP and one or two 19S RPs, which control the access of substrates to the CP (Finley, 2009; Tomko and Hochstrasser, 2013). 19S RPs recognize ubiquitin tags as well as unstructured domains of substrates and mediates their unfolding and translocation into the CP, with simultaneous deubiquitylation (Finley, 2009; Bhattacharyya *et al.*, 2014). The proteasome is a dynamic structure that undergoes conformational changes during substrate processing and that interacts with many other cellular proteins (Verma *et al.*, 2000; Matyskiela *et al.*, 2013; Marques *et al.*, 2009). Principle features of the proteasome and its subcomplexes are described below.

The 20S Core Particle: Structure and Catalytic Mechanism

The eukaryotic 20S CP (name refers to the sedimentation coefficient of the complex) is a barrel-shaped complex of about 700 kDa composed of 28 subunits. The complex bears identical halves made of two rings, one with seven distinct α subunits and one with seven distinct β subunits (Groll *et al.*, 1997). The α subunits form the outer platforms of the barrel and provide docking sites for regulator complexes, which control access of substrates and their translocation into the CP. In isolated CPs, the central pore is closed by N-terminal extensions of α subunits (Groll *et al.*, 2000). The two β rings form the catalytic chamber of the protease complex with two sets of three distinct active sites. These reside in the subunits β 1, β 2, and β 5 and cleave peptide bonds preferentially after acidic residues, after basic residues (tryptic activity), or after hydrophobic residues (chymotryptic activity) (Figure 2; Baumeister *et al.*, 1998). The proteasome is a threonine protease because its active sites employ the hydroxyl group of

Figure 2 The 26S proteasome: assembly chaperones, subunit composition and functions. Shown is a schematic drawing of the proteasome highlighting its subcomplexes, the 20S core particle (CP) and the 19S regulatory particle (RP). Subunit compositions of the 19S subcomplexes base and lid are given with indications of structurally characteristic domains or functions of the subunits. For the assembly chaperones, both their yeast and their human names (in brackets) are given. DUB, deubiquitylating activity; Ub, ubiquitin.

N-terminal threonine residues as nucleophiles (Seemuller *et al.*, 1995). Products of the digestion of a polypeptide within the proteasome are small peptides typically with an average size of 7–8 amino acid residues (Marques *et al.*, 2009). In some cases, however, the proteasome has also been shown to incompletely degrade (process) substrate proteins, a prime example being the 105 kDa precursor that is processed in a ubiquitin-dependent manner by the proteasome to yield the p50 subunit of NF- κ B (Palombella *et al.*, 1994).

The 19S RPs: Structure and Function

The main proteasome activator complex in eukaryotic cells is the 19S RP (or PA700). It is a ~700 kDa complex composed of at least 19 subunits, which can biochemically be separated into subcomplexes known as the 'base' and the 'lid' (Figure 2; Glickman *et al.*, 1998). The central unit of the base subcomplex is a hexameric ATPase complex of the AAA+ class (ATPases associated with different cellular activities). This part of the RP is formed by 6 distinct Rpt (Regulatory Particle ATPases) subunits, which make direct contact with the α ring surfaces of the CP. This Rpt ring is structurally related to the homo-hexameric PAN complex of the archaeon *Thermophilus acidophilum*, for which a structural model was developed based upon crystal structures of parts of the complex (Zhang *et al.*, 2009). The structural information deduced from the similarity to the PAN complex, as well as structural information on other subunits, together with cryo-electron microscopic analyses of the 19S RP, have recently enabled the generation of a structural model for the entire 19S RP (Figure 3; Lander *et al.*, 2012; Unverdorben *et al.*, 2014). Three of the 19S RP subunits (Rpt2, Rpt3, and Rpt5) share a so-called HbYX motif, in which a hydrophobic residue and a tyrosine are the third last and second last residue, respectively, at the C terminus. These

C-terminal extensions insert into distinct pockets between the α subunits thereby not only contributing to the stability of the complex, but also functioning as a key in the lock to open the central gate of the CP (Smith *et al.*, 2007). As a result, the central channel of the RPT complex aligns with the open gate in the α ring (Matyskiela *et al.*, 2013). Critical residues, including a tyrosine or phenylalanine residue followed by a hydrophobic residue and a glycine (Y/F-I/L/V-G), in loops of the Rpt subunits that align the central channel are thought to mediate binding of substrate domains and their subsequent unfolding and translocation into the 20S CP (Zhang *et al.*, 2009; Martin *et al.*, 2008; Eroles *et al.*, 2012). The latter is the result of ATP-driven conformational changes in the Rpt complex. Additional noteworthy structural features of the Rpt complex are three coiled coil structures each formed by pairs of Rpt subunits. These structural elements have important scaffold function mediating interaction with other regulatory particle non-ATPase (Rpn) subunits of the RP (Beck *et al.*, 2012; Lander *et al.*, 2012). Two subunits in the base, Rpn1 and Rpn2, that share solenoid and arm domains, can be considered as important scaffold subunits and platforms for the interaction with many proteins, including ubiquitin shuttling factors such as Rad23, ubiquitin ligases, and DUBs (Xie and Varshavsky, 2000; Leggett *et al.*, 2002; Elsasser *et al.*, 2002; Husnjak *et al.*, 2008; Lander *et al.*, 2012). Attached to these Rpn subunits are the two intrinsic ubiquitin receptor subunits. Rpn10 binds to ubiquitin chains via a ubiquitin-associated (UBA) domain found in many ubiquitin binding proteins, whereas Rpn13 employs a pleckstrin-homology (Pru) domain for ubiquitin recognition (Husnjak *et al.*, 2008; Schreiner *et al.*, 2008).

The lid is composed of 6 subunits bearing PCI (proteasome, CSN, eIF3) domains, two subunits with MPN (Mpr1/Pad1 N-terminal) domains (Glickman *et al.*, 1998; Scheel and Hofmann, 2005), and the structurally flexible Rpn15 subunit

Figure 3 Structure and functional modules of the 26S proteasome. Shown are various depictions of functional modules of the proteasome, which are derived from the X-ray crystal structures of the 20S core particle (CP) of *S. cerevisiae*, and a structural model of the 19S regulatory particle (RP) complex (Groll *et al.* (1997); Unverdorben *et al.* (2014)). (a), (c) Side views of the 19S RP, with base subunits shown in red and lid subunits shown in yellow. The two particles are matching in scale and rotation to join the 20S CP (shown in b) by up or down movements indicated by the arrows. (d) Side (upper part) and bottom views (lower part) of the hexameric Rpt ring. C-terminal HbYX (Y) motifs of Rpt (t) subunits are highlighted. (e) Top view on the heptameric α ring of the 20S CP showing the insertion sites of the HbYX (Y) motifs (in red). (f) Side view of the 19S RP highlighting the Rpt ring and ubiquitin receptor subunits Rpn10 and Rpn13 in the base, as well as of the Rpn13 subunit bearing deubiquitylating activity in the lid. (g) Cut open view of the 20S CP highlighting the active sites (in red) of three of the six active subunits. Figures were prepared using Pymol and PDB files 4CR2 (19S RP) and 1RYP (20S CP) and kindly provided by Paula C. Ramos.

(known as Sem1 in yeast, and Dss1 in humans). The latter has an important function for lid assembly (Tomko and Hochstrasser, 2014). The six C-terminal PCI domains form a horseshoe-like core structure from which the amino-terminal domains of the same subunits extend laterally to form an overall hand-like structure, which is attached to one side of the base reaching down to the CP α ring (Figures 3(a) and 3(c); Beck *et al.*, 2012; Lander *et al.*, 2012; Lasker *et al.*, 2012). The only clearly defined function of the lid subcomplex is provided by its Rpn11 subunit, which bears a metalloprotease activity that mediates substrate deubiquitylation. Rpn11 is positioned right above the entry into the Rpt complex (Lander *et al.*, 2012; Unverdorben *et al.*, 2014). This structural organization fits with biochemical results showing that ATP hydrolysis is critical for Rpn11 DUB activity indicating that substrate unfolding and translocation are coupled with deubiquitylation (Verma *et al.*, 2002; Yao and Cohen, 2002).

Alternative Regulatory Particles and Activators

Aside from the 19S RP, eukaryotic cells express several alternative proteasome activator proteins or complexes. PA200 (Blm10 in yeast) is a large monomeric protein with a C-terminal HbYX motif that has been implicated in DNA damage response and the degradation of some substrates (Ustrell *et al.*, 2002; Tar *et al.*, 2014; Lopez *et al.*, 2011). PA28 is a hexameric complex formed by two distinct subunits, expression of which is induced by interferon- γ . This complex takes part in the immune response by promoting the production of antigenic peptides (Groettrup *et al.*, 2010).

Assembly of the Proteasome

The assembly of the 26S proteasome from 47 individual (33 distinct) subunits is a complex process that involves a

remarkable array of dedicated assembly chaperones, all of which are not part of the final structure (Ramos and Dohmen, 2008; Murata *et al.*, 2009; Tomko and Hochstrasser, 2013; Figure 2). A special case is that of the CP chaperone Ump1 that is enclosed by newly formed proteasomes and degraded upon active site maturation (Ramos *et al.*, 1998).

Coordinated Transcriptional Control of Proteasome Gene Expression

Expression of proteasome genes is subject to a feedback control mechanism, in which the relevant transcriptional activator is itself a proteasomal substrate. This was first discovered in *S. cerevisiae*, where the Rpn4 protein, which was known to interact with 19S RP, was found to bind distinct elements in the promoters of proteasome subunit as well as many other genes (Mannhaupt *et al.*, 1999). Rpn4 is degraded by the proteasome both by ubiquitin-independent and ubiquitin-dependent mechanisms (Xie and Varshavsky, 2001; Ju and Xie, 2004). A similar, but in some aspects also distinct, feedback mechanism operates in mammalian cells, which use the transcription factor Nrf1 to control proteasome gene expression (Steffen *et al.*, 2010; Radhakrishnan *et al.*, 2010). Inactive Nrf1 resides in the membrane of the endoplasmic reticulum (ER). Its activation involves Cdc48/p97-dependent retrotranslocation into the cytosol and processing (Radhakrishnan *et al.*, 2014). However, if sufficient proteasomal activity is present in the cells, most of Nrf1 is degraded upon its arrival at the cytosolic surface of the ER. For both Rpn4 and Nrf1, inhibition or overload of the proteasome leads to stabilization and hence up-regulation of proteasome gene expression (Xie and Varshavsky, 2001; London *et al.*, 2004; Ju *et al.*, 2004; Steffen *et al.*, 2010; Radhakrishnan *et al.*, 2010).

The Immunoproteasome and Alternative CP Subunits

The proteasome has an important function in the immune system by supplying it with antigenic peptides, which are presented by major histocompatibility complex class I molecules on the surface of cells, e.g., upon infection with a pathogen (Goldberg *et al.*, 2002; Groettrup *et al.*, 2010; Basler *et al.*, 2013). Stimulation of an immune response transmitted by interferon- γ leads to the induction of three alternative β subunits (β 1i/LMP2/PSMB9, β 2i/MECL-1/PSMB10, and β 5i/LMP7/PSMB8), which assemble into newly formed CPs instead of their standard counterparts. The resulting immunoproteasome has slightly different specificities in the selection of substrate cleavage sites, which are thought to contribute to the generation of antigenic peptides (Goldberg *et al.*, 2002; Groettrup *et al.*, 2010; Basler *et al.*, 2013).

Another alternative subunit that leads to a distinct CP subtype termed the 'thymoproteasome' is β 5t. This subunit is expressed in the thymus in cortical epithelial cells (cTECs) and is important for the positive selection of CD8⁺ T cells (Murata *et al.*, 2007).

The only alternative α subunit identified thus far is α 4s/PSMB8, which is specifically expressed and incorporated into CPs in male germ cells. The functional significance of the novel proteasome subtype remains unclear as no difference in

biochemical activities were detectable in comparison to standard proteasomes (Uechi *et al.*, 2014). It was recently suggested, however, that 'spermatoproteasomes' characterized by the presence of α 4s and the PA200 activator promote acetylation-dependent degradation of core histones during spermatogenesis (Qian *et al.*, 2013).

The UPS as Drug Target

The Ubiquitin-Conjugation System

The UPS is involved in the control of many fundamental cellular processes including cell cycle, various signal transduction pathways, differentiation, and DNA repair. Thus, not surprisingly, deregulation of substrates or components of the UPS has been associated with various human diseases including rather complex disorders such as neurodegenerative diseases and various types of cancer as well as mono-genetic disorders such as cystic fibrosis and Angelman syndrome, a neurodevelopmental disorder (Bedford *et al.*, 2011; Ciechanover, 2013; Metzger *et al.*, 2014; Scheffner and Kumar, 2014). Accordingly, the UPS has become an attractive therapeutic target (see also section NEDD8). Depending on the UPS component affected/involved and the type of deregulation (inactivation or inappropriate activation), one can envision different strategies for molecular intervention. For example, 'loss-of-function' mutations in the genes encoding the RBR E3 ligase PARKIN and the HECT E3 ligase E6AP have been associated with autosomal recessive juvenile parkinsonism and Angelman syndrome, respectively (Ardley and Robinson, 2004; Bird, 2014). Since this presumably results in hyperactivation of respective substrate proteins, these would be preferred targets for pharmacological intervention. In contrast, amplification of the gene encoding the RING E3 ligase HDM2 (human Mdm2) has been associated with the development of osteosarcomas. Since HDM2 plays a prominent role in degradation of the tumor suppressor protein p53 (Brooks and Gu, 2011; Hock and Vousden, 2014), intervention with HDM2 activity or with the interaction of HDM2 with p53 appears to be the strategy of choice. Indeed, small molecules (termed Nutlins) binding to the p53-binding pocket of HDM2 interfere with HDM2-mediated ubiquitylation of p53 within cells (Shen and Maki, 2011). In more general terms, targeting the interfaces of E3-substrate interactions seems to be an attractive and most selective option in the treatment of diseases where enhanced degradation of a substrate contributes to the disease phenotype. Alternatively, due to the notion that in contrast to most of the E3 ligases (i.e. RING ligases), DUBs have a defined catalytic center and presumably show a certain degree of substrate specificity (as suggested by the number of DUBs encoded by the human genome), DUBs represent attractive therapeutic targets (Shanmugham and Ovaa, 2008).

The Proteasome

An important advance for the investigation of proteasome function and for its targeting in human diseases was the identification of specific natural and synthetic inhibitors (Vinitsky *et al.*, 1992; Rock *et al.*, 1994; Fenteany *et al.*, 1995).

One of the first identified synthetic peptide inhibitors of the proteasome, MG132, is still widely used in addressing proteasomal functions in cell biology (Goldberg, 2012). In the meanwhile, a wide repertoire of inhibitors has been established, all of which have in common that they target the active sites of the 20S CP (Borissenko and Groll, 2007; Moore *et al.*, 2008). The proteasome inhibitor Bortezomib/Velcade was the first approved drug that specifically targets the proteasome. It is successfully used in the treatment of multiple myeloma, a cancer affecting blood cells that secrete large amounts of aberrant antibody polypeptides (Goldberg, 2012). One reason that these lymphoma cells are hypersensitive to proteasome inhibitor appears to be that they require high proteasome activity to cope with the abnormal antibody polypeptides generated by ERAD. Interfering with this process by proteasome inhibition drives these cells into apoptosis.

More recent advances are inhibitors that provide a species- or subtype-specific targeting of proteasomes. One such class of inhibitors was shown to be specific for the proteasome of the eubacterial human pathogen *Mycobacterium tuberculosis* (Lin *et al.*, 2009). Another inhibitor was shown to preferentially inhibit the immunoproteasome (Muchamuel *et al.*, 2009). Both types of inhibitors have the potential for the treatment of specific human diseases.

Conclusion

The past three to four decades have witnessed the transformation of a research field (ubiquitin-mediated protein degradation) that was studied by only a few pioneering groups into one of the most intensely studied research areas. Similarly, while in the beginning ubiquitin was assumed to function only in proteasome-mediated degradation, it has become clear that many aspects or properties of a protein can be affected by modification with ubiquitin or UBLs. In addition, ubiquitylation is not a uniform posttranslational modification (e.g., such as phosphorylation) but rather comes in many different modes/types and involves an ever-increasing number of enzymes and proteins. The complexity of the UPS, however, also poses a number of challenging questions. For example, do different types of ubiquitylation signal a modified protein for distinct fates or do they have overlapping/redundant functions? How are the different types eventually decoded? Does this solely depend on proteins that selectively recognize different types of ubiquitylation or do additional properties of the modified proteins contribute? Furthermore, the high number of putative E3s provides the UPS with the ability to operate in a highly substrate-specific manner. Nonetheless, for most E3s, the substrates have not yet been identified (and vice versa) and, at least in some cases, E3s appear to have overlapping sets of substrates. For example, more than 10 E3s have been reported to be involved in p53 ubiquitylation/degradation (Brooks and Gu, 2011; Hock and Vousden, 2014). Thus, besides determining the potential substrate spectra of E3s and how these are affected by crosstalk with other posttranslational modifications, a major challenge will be in defining when (e.g., during cell cycle or differentiation) and to what extent a given E3 contributes to the degradation of a given protein. The proteasome is a central factor in the UPS

and a valuable drug target. Recent studies have led to major advances in the understanding of its structure and function. Yet, many challenging questions remain open regarding the recognition of distinct types of substrates (e.g., ubiquitin-independent *versus* ubiquitin-dependent) and their competition in a cellular context, as well as concerning the transcriptional and posttranscriptional regulation of the proteasome.

Glossary

Endoplasmic reticulum-associated degradation

(ERAD) A collection of related processes that participate in the recognition and degradation of proteins localized in the endoplasmic reticulum. The ERAD of all substrates generally requires for basic steps: substrates are recognized (and brought to the ER membrane, if luminal), removed from the ER, ubiquitinated, and degraded by the cytosolic proteasome.

Native fold The properly folded and biologically active conformation of a protein, usually it is also the most thermodynamically stable.

Proteostasis (protein homeostasis) Refers to the maintenance of optimal protein biological activity and the cellular mechanisms that are responsible for this. Environmental alterations can have a profound impact on the native structure of proteins and on the folding capacity of the cells. Cells have developed a network of molecular chaperones, enzymes, and signal transducing components that participate in the synthesis, folding, quality control, and degradation of all cellular proteins, and that are able to rapidly respond to environmental stress, such that protein's biological function is maintained.

Quality control code The collection of signals displayed by a polypeptide (encoded or introduced posttranslationally) that dictate its movement through the secretory pathway and its interaction with the folding and quality control machineries. These include the ER targeting sequences, the *N*-glycosylation sequons, the exposed hydrophobic patches, the ER retention/exit signals, and the glycan and polyubiquitin chains, among others.

Retro-translocation Also known as dislocation, is a term that refers to the processes by which ER proteins are extracted from the ER into the cytosol.

Sequon A sequence of amino acids *N*-X-S/T (Asparagine-X-Serine or Threonine) found in a polypeptide, where X cannot be Proline, to which *N*-linked glycans are appended by the oligosaccharyltransferase.

Translocation Movement of a polypeptide across the ER membrane and into the ER lumen.

Translocon A proteinaceous channel in the ER membrane through which secretory polypeptides enter the ER. It is composed of a Sec61 heterotrimeric core and several associated components.

Introduction

Endoplasmic reticulum-associated degradation (ERAD) is the process that refers to the identification of proteins localized in the endoplasmic reticulum (ER) and their cytosolic destruction. One of the most critical tasks of ERAD is to aid in the selective degradation of misfolded proteins that enter the secretory pathway. If these misfolded proteins are not eliminated, they may accumulate in the ER, limiting its folding capacity by sequestering ER chaperones or by aggregating. Further, the accumulation of misfolded proteins in the ER can trigger a cellular stress response that can lead to apoptosis if unmitigated (Fribley *et al.*, 2009). Thus, the carefully controlled intracellular destruction of proteins by ERAD helps prevent the toxicity associated with aberrantly folded secretory proteins and their potential detrimental effect on cellular homeostasis.

Many human diseases are associated with the ERAD pathway. Some of these diseases occur due to mutations in secretory proteins that result in protein misfolding and that turn them into ERAD substrates. One disease in this class is Gaucher disease, a lysosomal storage disorder (Ron and Horowitz, 2005; Futerman and van Meer, 2004). In other cases the ERAD machinery can be too efficient and prematurely eliminate proteins that would eventually be able to fold. For example,

the slowly folding $\Delta F508$ variant of the cystic fibrosis transmembrane conductance regulator (CFTR) is prematurely degraded by ERAD, leading to cystic fibrosis (Jensen *et al.*, 1995; Ward *et al.*, 1995). Other human diseases are associated with mutations in the ERAD or the quality control machinery themselves. For example, mutations that affect *N*-linked glycosylation (an ER posttranslational modification linked to quality control and ERAD) can cause a variety of symptoms, including dysmorphism, encephalopathy, and organ disorders (Imbach *et al.*, 1999; Freeze *et al.*, 2014). Together, a growing number of human diseases, including neurological, respiratory, cardiovascular, and liver diseases, among many others (Guerriero and Brodsky, 2012; Jucker and Walker, 2013) are linked to ERAD and protein quality control in the secretory pathway.

The function of the secretory pathway was elucidated in the 1970s and early 1980s. This pathway can be grossly outlined as a port of entry (the ER), intermediate entities (the Golgi complex and vesicles), and a port of exit (the plasma membrane or the extracellular space). However, as we discuss below, the secretory organelles and vesicular intermediates do not simply provide a route for proteins out of the cell or to become embedded within lipid bilayers in the organelles or plasma membrane. Instead, these compartments play a critical role in preparing secretory proteins for export and in their

quality control. Research on this topic began with Palade's ground-breaking use of radioisotopes to outline the pathway (Palade, 1975), Blobel's innovative development of a cell-free system to uncover the first secretion signals and receptors (Blobel and Dobberstein, 1975), and Schekman's elegant application of yeast genetics to characterize components that constitute the secretory pathway (Novick *et al.*, 1980). By the mid 1980s, many research groups focused on determining how specific components mediate the selective versus non-selective trafficking of proteins through the ER (Pelham, 1989; Pfeffer and Rothman, 1987; McCracken and Kruse, 1989). Increasing evidence indicated that mutated proteins of medical importance accumulated in the ER (Hurtley and Helenius, 1989; McCracken *et al.*, 1989), and that mutated proteins that normally pass through the ER were apparently turned-over (Cheng *et al.*, 1990; Needham and Brodsky, 2013). It was soon clear that mutated ER proteins were degraded (McCracken and Kruse, 1993; Finger *et al.*, 1993; Hampton and Rine, 1994; Klausner and Sitia, 1990). Because lysosomal/vacuolar enzymes were dispensable for this event, it was tempting to speculate that degradation took place within the ER. However, there was no evidence of a proteolytic quality control system housed within the ER. Because of the uncertainty surrounding the nature of the protease, we named this process ER-associated degradation, or ERAD (McCracken and Brodsky, 1996).

Through the use of yeast genetics and mammalian cell systems, and by employing both *in vivo* and *in vitro* tools, compelling evidence emerged that the cytosolic proteasome provides the proteolytic activity for ERAD (Werner *et al.*, 1996; Hiller *et al.*, 1996; McCracken *et al.*, 1996; Jensen *et al.*, 1995; Ward *et al.*, 1995; Wiertz *et al.*, 1996a; Sommer and Jentsch, 1993). This discovery came as a complete surprise. Although integral membrane proteins in the ER could access a cytosolic protease, it was unexpected that soluble secreted proteins could also be degraded by the proteasome. The solution to this problem was that soluble proteins were recognized within the ER and then returned to the cytosol via an event termed 'retro-translocation' or 'dislocation.' Over the ensuing years, a significant effort has been devoted to understanding how diverse ERAD substrates are selected, retro-translocated, and targeted to the proteasome.

In the end, it was evident that ERAD represented 'an unconventional route' (retro-translocation from the ER) to a 'familiar fate' (misfolded protein degradation by the cytosolic proteasome) (Werner *et al.*, 1996; Hiller *et al.*, 1996). Because defects in the ERAD pathway exhibited synthetic, negative effects when ER stress response pathways were disabled (Travers *et al.*, 2000), it also became clear that ERAD was one of the two critical components that maintain ER homeostasis, the other being the unfolded protein response (UPR) (Walter and Ron, 2011). Together, ERAD and the UPR minimize the potentially detrimental effects of protein misfolding in the secretory pathway. Nevertheless, the ERAD pathway and ERAD-like mechanisms also regulate the stability (and thus activity) of wild type, functional proteins in the secretory pathway (Chen *et al.*, 2011a; Hampton, 2002; Lemberg, 2013) and can also be hijacked by pathogens (Noack *et al.*, 2014).

In this article, we will provide an overview of the processes that shape a secretory protein as it travels through the early secretory pathway. During this journey, secretory proteins

display signals that are scanned by numerous binding partners. These signals not only dictate if a protein will enter the ER, but also if it should be posttranslationally modified and transported to later compartments in the secretory pathway, or if it should instead be degraded. Deciphering this 'quality control code' is a critical task dutifully performed by ER protein quality control mechanisms and ERAD. It should be noted that most of the information on the function of the secretory pathway and quality control mechanisms has been obtained through the use of both the yeast *Saccharomyces cerevisiae* and mammalian cells. As expected, the mammalian system is more complex and thus there are more enzymes and chaperones involved in each process, and the ERAD-L, ERAD-C, and ERAD-M processes, which were defined in yeast, are poorly defined in mammalian cells. However, general processes are highly conserved and orthologs of the most relevant genes involved in these processes are found in both organisms. Here we discuss both systems, provide the name of the orthologs when available, and point out the differences between both models when relevant.

The Manufacturing of a Secretory Protein

Targeting and Entering the ER: The Beginning of a Perilous Journey

The first challenge that secretory proteins must overcome on their way through the secretory pathway is finding and then inserting into the ER. To solve the first problem, secretory proteins possess signals that target them to the ER. These signals influence not only if the protein will enter the ER using co- or posttranslational mechanisms, but also what chaperones will protect and guide them to the ER, and in what folding state they will reach this organelle (Cross *et al.*, 2009). The strength of the signal depends on its length, hydrophobicity, topology, or amino acid composition, and each signal is recognized by specific protein complexes and chaperones (Akopian *et al.*, 2013; Ng *et al.*, 1996; Hegde and Bernstein, 2006). The majority of proteins are targeted to the ER via an N-terminal signal sequence (SS) (Figure 1(a)). The most prevalent ER targeting mechanism is the signal recognition particle (SRP) pathway, a co-translational mRNA/protein partitioning mechanism that depends on the secretory protein's SS (Blobel *et al.*, 1979; Akopian *et al.*, 2013; Noriega *et al.*, 2014). In this pathway, soon after the SS is synthesized by the ribosome it is bound by the SRP. Binding stalls the ribosome, which prevents further translation (Siegel and Walter, 1986; Walter *et al.*, 1981) (Figure 1(a)). The SRP tethers the ribosome-nascent chain complex (RNC) to the ER through interaction with the SRP receptor at the ER surface (Gilmore *et al.*, 1982). There, the RNC is transferred to the Sec61 translocon (see below). The SRP is then recycled, and mRNA translation continues while the nascent polypeptide is translocated (i.e. transferred across the membrane) into the ER lumen, or is inserted into the ER membrane (Crowley *et al.*, 1994; Jungnickel and Rapoport, 1995) (Figures 1(a) and 1(b)). However, recent evidence demonstrated that ~40% of secretory proteins in yeast reach the ER in an SRP-independent manner (Ast *et al.*, 2013). Most of these proteins contain a tail

Figure 1 Translocation, folding, and ER exit of a secretory protein. (a) The signal recognition particle (SRP) recognizes the signal sequence (SS) emerging from the ribosome, and delivers the ribosome-nascent chain complex to the SRP receptor (SRP Rc) near the Sec61 translocation channel. The SRP is then recycled. (b) The polypeptide is translocated into the ER lumen and posttranslationally modified: the SS is cleaved by the signal peptidase (SPase), N-X-S/T sequons are *N*-glycosylated by the oligosaccharyltransferase (OST), and PDI facilitates disulfide bond formation. The Hsp70 chaperone BiP protects the incoming polypeptide from aggregation and is required for translocation. BiP is tethered to the translocon through its interaction with the transmembrane protein Sec63, and this interaction is required for proper protein translocation. (c) The folding of glycosylated and unglycosylated polypeptides is surveyed by BiP and its co-chaperones. ATP-bound BiP accepts substrates that may be delivered by Hsp40s co-chaperones. BiP binding to the Hsp40s and the substrate stimulates ATP-hydrolysis, forming a high affinity ADP-BiP-substrate complex. Nucleotide exchange factors (NEFs) accelerate ADP release. This reduces Hsp70's affinity for the substrate, facilitates substrate release, and recycles ATP-BiP. At this point the substrate may still not be properly folded, requiring additional cycles of Hsp70 binding and release. (d) In mammalian cells, glycoproteins are delivered to the CNX/CRT/UGGT quality control machinery (glycoprotein QC) (also see [Figure 2\(b\)](#)). Folded substrates exit the ER at ER exit sites (ERES) (known as transitional ER in yeast), where they are loaded into COPII vesicles with the help of cargo receptors (Cargo Rc). (f) In yeast, misfolded unglycosylated substrates can be *O*-mannosylated by Pmt1 and Pmt2 and targeted for ERAD (UPOM). (g) Alternatively, misfolded substrates may be targeted to ERAD due to prolonged chaperone interactions independently of the glycan.

anchor (TA) sequence (a single C-terminal transmembrane domain) or a glycosylphosphatidylinositol (GPI)-anchoring sequence. TA and GPI proteins are targeted to the ER via the guided entry of TA proteins (GET) pathway ([Ast et al., 2013](#); [Hegde and Keenan, 2011](#); [Schuldiner et al., 2008](#); [Wang et al., 2014](#)). Small soluble proteins can also be posttranslationally translocated into the ER, but their ER targeting mechanism remains poorly elucidated ([Deshaies et al., 1988](#); [Panzner et al., 1995](#)). Further, some secretory proteins reach the ER through targeting sequences in their mRNAs ([Weis et al., 2013](#); [Kraut-Cohen et al., 2013](#)).

The port of entry to the ER lumen for most secretory proteins which are translocated co- or posttranslationally is a

proteinaceous pore in the membrane called the Sec61 translocon ([Figure 1\(b\)](#)). The translocon is an oligomeric protein-conducting channel composed of a conserved Sec61-containing heterotrimeric core and associated components ([Rapoport, 2007](#)). The associated components perform a variety of functions. For example, the ribosome and the Hsp70 BiP (via the Sec63 anchor at the ER membrane) ratchets proteins into the ER (since the pore itself is passive); the signal peptidase complex removes the SS from the translocating nascent chain; and the oligosaccharyltransferase (OST) *N*-glycosylates substrates at specific motifs (see below) ([Figure 1\(b\)](#)). The yeast translocon also associates with protein mannosyltransferases which *O*-mannosylate translocating polypeptides ([Loibl et al., 2014](#)).

The yeast posttranslational translocon also contains the transmembrane proteins Sec62, Sec63, Sec71, and Sec72 (Deshaies and Schekman, 1989; Green *et al.*, 1992). In order to insert transmembrane segments into the lipid bilayer, the translocon must open laterally (Shao and Hegde, 2011). On the other hand, TA-proteins insert into the ER membrane independently of the translocon, using the yeast GET pathway or a homologous family of proteins in mammals (Hegde and Keenan, 2011). Given the variety of ER targeting signals and the structural diversity of secretory proteins, it has become clear that the ER targeting mechanisms and translocation pathways are more diverse than previously expected.

Secretory proteins must be maintained in a translocation/insertion competent state during and after translation. This is a challenging task, since these proteins contain aggregation-prone hydrophobic regions, including ER targeting signals (Hegde and Bernstein, 2006). Translocation competence is facilitated by dedicated molecular chaperones in the cytosol and the ER, which include members of the heat-shock protein (Hsp) 70 family and Hsp70 regulating co-factors, such as the Hsp40s and nucleotide exchange factors (NEFs) (Zimmermann *et al.*, 2006; Figure 1(c)). Hsp70 chaperones bind stretches of hydrophobic amino acids that are exposed in non-native proteins (Flynn *et al.*, 1991). Hsp70s bind and then release substrates in an ATP-dependent manner, thereby preventing aggregation (Hartl *et al.*, 2011; Figure 1(c), the Hsp70 cycle). Although chaperones can recognize any substrate presenting hydrophobic patches or segments, there is also client-specificity driven by cofactors. For example, the ubiquitous and abundant Hsp70s are regulated by a considerably larger number of Hsp40s and NEFs, which diversify and fine-tune the Hsp70's client choice (Kampinga and Craig, 2010). Chaperones play other critical roles during protein biogenesis and quality control, including: aiding *de novo* folding, re-folding, and oligomeric protein assembly; dissolving protein aggregates; and redirecting misfolded proteins for degradation. Chaperones can also chaperone other chaperones. For example, the ER resident Hsp70 BiP is required for the stability of the ER localized AAA+ ATPase torsinA, a protein involved in the human neurological disease Early Onset Torsion Dystonia (Zacchi *et al.*, 2014). Chaperones are also required for protein translocation. For example, BiP is required for both co- and posttranslational translocation (Brodsky *et al.*, 1995; Matlack *et al.*, 1999), possibly by regulating the activity of the translocon (Alder *et al.*, 2005; Figure 1(b)). Further, a specialized set of chaperone-like proteins localized in the ER act on the translocated polypeptide, including the lectins, which bind glycosylated (and in some cases non-glycosylated) proteins, and the protein disulfide isomerases (PDIs), which form and isomerize disulfide bonds (Buck *et al.*, 2007; Figure 1(b)). Together, the ER chaperones cooperate in the productive folding of secretory proteins and in preventing the formation of misfolded intermediates by recognizing and targeting these substrates for ERAD.

The N-Glycosylation Quality Control Pathway

Once in the ER, secretory proteins can be posttranslationally modified by lipidation, the formation of disulfide bonds, cleavage of the SS, and O- and N-linked glycosylation. Most secretory proteins are modified with high mannose-containing

glycans, a process carried out by the membrane-bound OST complex (Kelleher and Gilmore, 2006; Figure 1(b)). The biological roles of N-glycans are diverse. Bulky and hydrophilic sugar moieties can mediate protein-protein recognition, can stabilize some elements of secondary structure, and can improve protein solubility by stabilizing hydrophobic regions (Imperiali and Rickert, 1995). In most organisms the catalytic subunit of OST, STT3, transfers the oligosaccharide Glc₃Man₉GlcNAc₂ (where Glc, Man, and GlcNAc are glucose, mannose, and N-acetyl glucosamine, respectively (Figure 2(a))) from a dolichol-linked donor to the side chain of an Asn displayed within a sequon. The sequon is an Asn-X-Ser/Thr sequence, where X can be any residue except Pro. Mammals express two isoforms of STT3, STT3-A and STT3-B, which ensure a high degree of sequon occupancy (Ruiz-Canada *et al.*, 2009). While STT3A activity is mainly evident co-translocationally, STT3B is most active after a polypeptide is released from the Sec61 translocon. High mannose glycans are generally trimmed-down to the core glycan (Man₃GlcNAc₂) as they transit through the early secretory pathway. Golgi-resident glycosyltransferases complete the formation of the complex glycans usually found in mature glycoproteins. Thus, although all glycoproteins initially contain a common glycan, this structure is sharply diversified as glycoproteins traffic to their final destinations.

Why would the cell transfer a glycan that ends up being trimmed to the core, consuming energy in the process? The answer to this question emerged from the discovery that high mannose glycans are used as a platform to encode information on the folding status of glycoproteins. In other words, the glycan constitutes a signal in the 'quality control code,' and is the basis of the glycoprotein quality control system (Figures 1(d) and 2, also see below). The glycoprotein quality control process can be summarized as follows: N-glycans are modified by glycosyltransferases and glycosidases depending on the conformation and the age of the glycoprotein. Several lectins recognize the resulting N-glycans, prevent the premature exit from the ER of folding intermediates, aid in the folding process, and permit export to the Golgi or, alternatively, escort misfolded glycosylated proteins to the ERAD machinery (Figure 2(b)).

The glycoprotein quality control system provided the first demonstration that N-glycans shape a glycoprotein's fate (Caramelo and Parodi, 2008; Aebi *et al.*, 2010). Immediately after the Glc₃Man₉GlcNAc₂ N-glycan is appended onto a secretory protein, the outermost Glc residue is cleaved by glucosidase I (GI), generating Glc₂Man₉GlcNAc₂ (Figure 2). GI is localized at the ER membrane and associates with the translocon, and this ensures that the first deglycosylation step occurs rapidly (Dejgaard *et al.*, 2010). The second Glc residue is hydrolyzed by glucosidase II (GII), thus generating the monoglucosylated glycan Glc₁Man₉GlcNAc₂ (Figure 2(a)). Because it is the monoglucosylated form of the glycan the one that enters the CNX/CRT/UGGT quality control cycle (see below), the diglucosylated intermediate had not previously received much attention. However, Malectin, another ER resident lectin, specifically recognizes this diglucosylated moiety (Schallus *et al.*, 2008). Although the biological role of Malectin binding is unclear, Malectin association may regulate the flux of glycoproteins into subsequent processing steps (Chen *et al.*, 2011b). Regardless, the monoglucosylated moiety is then

Figure 2 *N*-glycan quality control. (a) A schematic representation of the *N*-glycan transferred by OST. Residues relevant for quality control decisions are highlighted: (a) is required for CNX/CRT binding, (b) is required for UGGT binding, and (c) is required for OS-9/XTP3-B binding. The types of sugars and linkages are shown, as well as the sites where quality control enzymatic reactions take place (the linkages cleaved by glycosydases (GI and GII) and mannosydases (ER ManI and EDEMs)). (b) Glycoprotein folding is assisted by the CNX/CRT/UGGT cycle and, if unsuccessful, it is terminated by mannose trimming. *N*-glycans are processed by Glucosidase I and II (GI and GII), which produce a monoglucosylated *N*-glycan, Glc₁Man₉GlcNAc₂ that is a ligand for CNX/CRT. GII removes the last Glc residue, preventing CNX/CRT re-binding. If the glycoprotein is folded it can exit the ER. If it remains unfolded, UGGT reglucosylates it (residue 'a'). During these cycles, the misfolded Man₉GlcNAc₂ substrate may be de-mannosylated by ER α_{1,2} mannosidase I. Removal of 'b' irreversibly blocks UGGT binding, and therefore the substrate is now targeted for ERAD or ER exit. EDEM trims the substrate further, eventually exposing residue 'c', an α_{1,6} linked mannose, which is a ligand for OS-9 (Yos9) and XTP3-B and, thus, an ERAD substrate.

recognized by the ER resident lectins calreticulin (CRT) or its membrane-bound paralog calnexin (CNX) (Figure 2(a), residue 'a' is required for CNX/CRT binding) (Michalak *et al.*, 1999). CNX/CRT retain the monoglucosylated glycoprotein in the ER and improve folding efficiency by preventing aggregation and by recruiting ERp57, a PDI homolog that helps form correct disulfide bridges (Coe and Michalak, 2010). Eventually, the last Glc residue is cleaved by GII, releasing the glycoprotein from CNX and CRT (Figure 2). At this point, proteins displaying a native fold can enter COPII vesicles that bud from the ER membrane for delivery to the Golgi (Figure 1(e)). *N*-glycans also play a role during this event, since ER export via COPII vesicles in some cases is mediated by other lectins (ERGIC-53, VIP36, and VIPL) that recognize high-mannose structures (Hauri *et al.*, 2002). In contrast, unfolded or partially folded proteins are re-glucosylated by the enzyme UDP-Glc:glycoprotein glucosyltransferase (UGGT), which

adds back a Glc and regenerates the monoglucosylated substrate that interacts with CNX and CRT (Caramelo and Parodi, 2008; Figure 2). UGGT operates as a folding sensor that combines the activity of a glucosyltransferase with the specificity of a molecular chaperone. *In vitro* assays showed that UGGT preferentially recognizes exposed hydrophobic stretches displayed by advanced folding intermediates (Caramelo *et al.*, 2003; Ritter and Helenius, 2000; Taylor *et al.*, 2004; Taylor *et al.*, 2003), and cellular studies suggested that UGGT focuses its activity on advanced folding intermediates after release from BiP (Labriola *et al.*, 2011). Therefore, BiP and the CNX/CRT/UGGT cycle can cooperate during the folding of nascent proteins in the ER (Figures 1(c), 1(d), and 2). Interestingly, *S. cerevisiae* lacks a CRT ortholog as well as functional orthologs of CNX and UGGT: Cne1 (the CNX ortholog) plays a more limited role in ERAD and Kre5 (the UGGT ortholog) appears to lack enzymatic activity (Parlati *et al.*, 1995;

Fernandez *et al.*, 1994). Nevertheless, yeast can efficiently fold glycoproteins and dispose of misfolded *N*-glycosylated proteins, indicating that other chaperones or alternative mechanisms are in place in yeast that compensate for the lack of the CNX/CRT/UGGT cycle.

The cycle of deglycosylation and reglycosylation by GII and UGGT can continue until the protein folds or until it is marked for ERAD. Glycoprotein commitment to the ERAD pathway is modulated by the trimming of mannose residues (Hosokawa *et al.*, 2010a; Stigliano *et al.*, 2011). During this commitment step, ER α mannosidase (ER α ManI) (Mns1p in yeast) first cleaves the α 1,2-mannose residue located in the B branch of the *N*-glycan to generate Man₈GlcNAc₂ (Figure 2). The concentration of this enzyme in a specialized ER sub-compartment may allow further trimming of the *N*-glycans until Man₆GlcNAc₂ or Man₅GlcNAc₂ are generated (Avezov *et al.*, 2008). Mannose trimming can negatively impact GII activity, favoring the pro-folding CNX/CRT-ligand interaction (Stigliano *et al.*, 2011). Mannose trimming may also be carried out by EDEM1, EDEM2, or EDEM3, all of which are members of the EDEM (ER degradation-enhancing α -mannosidase-like protein) family (Htm1/Mnl1 in yeast) (Hirao *et al.*, 2006; Hosokawa *et al.*, 2010b; Molinari *et al.*, 2003). In fact, CNX can transfer glycoproteins directly to EDEM (Oda *et al.*, 2003). Indeed, recent evidence indicates that EDEM2 can also perform the initial de-mannosylation of the substrate from Man₉GlcNAc₂ to Man₈GlcNAc₂, which can be followed by further mannose trimming by EDEM3 (Ninagawa *et al.*, 2014). A point of no return in these reactions is the cleavage of the α 1,2-mannose residue located in the A branch of the *N*-glycan (Figure 2(a), residue 'b'), since it precludes UGGT action and definitively removes glycoproteins from the CNX/CRT/UGGT cycle. In contrast, cleavage of the α 1,2-mannose residue located in the C branch of the *N*-glycan exposes a terminal α 1,6-mannose residue (Figure 2(a), residue 'c'). The resulting *N*-glycan is recognized by the lectins OS-9 (Yos9 in yeast) and XTP3-B, which escort terminally misfolded glycoproteins to the ERAD machinery (Hosokawa *et al.*, 2010a; Bhamidipati *et al.*, 2005; Clerc *et al.*, 2009; Figure 2). Interestingly, OS-9, XTP3-B, and the EDEMs can also bind substrates outside of their lectin domain and, instead, they can use this domain to associate with glycosylated SEL1L (Hrd3 in yeast), the substrate acceptor component of the retrotranslocon (Figure 4(b); Aebi *et al.*, 2010; Christianson *et al.*, 2008; Cormier *et al.*, 2009). In this way, the lectin domain would bring substrates to the retrotranslocon instead of selecting ERAD substrates. This helps explain how these lectins are also involved in the degradation of unglycosylated substrates (see below).

A crucial, yet poorly understood event in this cycle is how this glycoprotein quality control system distinguishes terminally misfolded proteins from folding intermediates. This issue is particularly important for proteins that are difficult to fold, such as multidomain proteins with high β -sheet content or that display an intricate connectivity of disulfide bridges. The simplest model is that the time a protein resides in the ER plays the most important role in the ERAD decision. In comparison with GI and GII, the activity of ER ManI and EDEMs is low, which led to the 'mannose timer' hypothesis for glycoprotein quality control (Wu *et al.*, 2003; Figure 2(b)). According to this model, if a protein spends too much time

attempting to fold, mannose residues are eventually trimmed and the protein is sent to the ERAD machinery. However, this model fails to explain why native ER resident proteins avoid degradation. Perhaps a signal other than mannose trimming is required or, alternatively, misfolded glycoproteins are simply better substrates for mannose trimming.

ER Exit: The Continuation of a Productive Journey

Once posttranslationally modified and folded, proteins leave the ER to continue through the secretory pathway toward their next destination: the Golgi complex (Figure 1(e)). ER exit occurs in COPII vesicles that bud from specific ER regions, known as ER exit sites (ERES) in mammals, and the transitional ER in lower organisms (Orci *et al.*, 1991; Bannykh *et al.*, 1996). Specialized molecular machinery is tethered to these sites, where cargo is sorted and most misfolded proteins are selectively excluded from secretory vesicles. To exit the ER, cargo utilize spherical COPII-coated transport vesicles (Lord *et al.*, 2013), although there are examples of COPII-independent ER exit mechanisms that bypass the Golgi (Grieve and Rabouille, 2011). In the canonical pathway, liberated COPII vesicles are tethered to pre-Golgi compartments (the mammalian ER-Golgi intermediate compartment (ERGIC) or the yeast *cis*-Golgi) through interactions with receptors (Barlowe *et al.*, 1994; Beckers *et al.*, 1989; Eakle *et al.*, 1988; Sollner *et al.*, 1993; Wilson *et al.*, 1989).

Similar to ER targeting and glycan signals, the ER exit/retention signals encoded in the proteins are fundamental parts of the 'quality control code.' Proteins normally retained in the ER may exit through bulk flow in COPII vesicles but are retrieved via COPI coated vesicles (Aridor *et al.*, 1995; Letourneur *et al.*, 1994; Waters *et al.*, 1991). ER retrieval is dictated by retrieval sequences: the C-terminal K/HDEL sequence (primarily for soluble proteins), and the C-terminal di-Lys and N-terminal di-Arg motifs (primarily for membrane proteins) (Munro and Pelham, 1987; Jackson *et al.*, 1990; Michelsen *et al.*, 2005; Schutze *et al.*, 1994). There are also sequence-independent mechanisms for ER retention which depend on several factors, including the physicochemical characteristics of the transmembrane domains (e.g., length and hydrophobicity), the membrane lipid composition, and alterations in ER membrane curvature at ERES, which limit the partition of specific membrane-associated monotopic proteins (Vander Heyden *et al.*, 2011; Ronchi *et al.*, 2008; Sato *et al.*, 1996; Rayner and Pelham, 1997).

The sorting and selection of secretory proteins is carefully controlled. These substrates use a variety of signals to exit the ER. Some transmembrane proteins expose ER export signals to the cytosol that are recognized by COPII components. In turn, soluble secretory proteins can expose exit signals in the ER lumen, which are recognized by cargo receptors that associate with COPII components (Figure 1(e); Bonifacino and Click, 2004; Barlowe, 2003; Zanetti *et al.*, 2012). Although most misfolded proteins are retained in the ER and degraded via ERAD, some misfolded proteins are exported if ER exit sequences are displayed (Kincaid and Cooper, 2007). In fact, the degradation of select ERAD substrates may require ER-to-Golgi traffic (Haynes *et al.*, 2002; Taxis *et al.*, 2002), but the nature of

Figure 3 Basic steps during ER associated degradation in yeast. (a) ERAD substrates can expose lesions in the ER lumen (ERAD-L), ER membrane (ERAD-M), or cytosol (ERAD-C), and are recognized by distinct recognition factors (including chaperones and lectins), some of which deliver the substrate to the ER membrane for retro-translocation into the cytosol. (b) Retro-translocation is thought to occur through a channel in the ER membrane and is intimately connected with substrate ubiquitination. Some of the targeting factors may also help unfold the substrate. Ubiquitination occurs before or during substrate retro-translocation. (c) Ubiquitination requires the concerted action of E1, E2s (associated to the ER via a transmembrane domain or a membrane adapter (E2 Ad)) and ER membrane-resident E3 enzymes. Some cytosolic E2s and E3s also play a role in ERAD. The ubiquitinated substrate may tether the Cdc48 complex to the retro-translocation channel, where Cdc48 drives substrate retro-translocation. (d) A Cdc48-associated cofactor deglycosylates the substrate, and the Cdc48 complex delivers the substrate to the proteasome where it is de-ubiquitinated by proteasomal enzymes and degraded into shorter peptides.

this phenomenon is unclear. In addition, ER exit is used to regulate ERAD. For example, the lectins EDEM1 and OS-9 are exported from the ER in a COPII-independent manner and degraded via selective autophagy or in late endosomes/lysosomes, a process that down-regulates ERAD activity (Cali *et al.*, 2008; Zuber *et al.*, 2007; Park *et al.*, 2014; Bernasconi *et al.*, 2012). Unassembled subunits of oligomers can also be exported from the ER with EDEM1 in a COPII-independent manner and degraded via autophagy (Le Fourn *et al.*, 2013). Therefore, folding and export mechanisms work together in a fragile and strongly interdependent equilibrium to mediate ER protein quality control.

Unforgivable Errors: The ERADication of an Unfolded Protein

ERAD is a general term encompassing a variety of related mechanisms that lead to the proteasomal degradation of ER proteins. In all cases the ERAD pathway consists of four steps: substrate recognition, retro-translocation into the cytosol, ubiquitination, and proteasomal degradation (Figure 3). Each step is considered in the following sections.

Substrate Selection

The great majority of polypeptides enter the protein-rich environment in the ER in a non native state. Even under the best

conditions folding is inefficient, and polypeptides transition through folding intermediates before attaining their native conformations (Hartl *et al.*, 2011). During this time, hydrophobic, aggregation-prone sequences that will become buried in the native structure are exposed. Chaperones bind hydrophobic amino acid stretches, but are unable to distinguish a terminally misfolded protein from a folding intermediate. Similarly, although the CNX/CRT/UGGT cycle can recognize protein folding status, the decision to target misfolded glycoproteins for ERAD still depends on stochastic mannose trimming events. Consequently, many wild type proteins are probably targeted for degradation, even though considerable energy has been spent on the synthesis, translocation, post-translational modification, and chaperoning of a sluggish polypeptide/folding intermediate. However, because misfolded polypeptides pose a threat to cellular viability that is more costly than re-synthesizing a polypeptide, it is critical that any misfolded protein – even if it is a wild type protein – is eliminated by ERAD (Brodsky, 2012).

Location, location, location

The ERAD substrate recognition machinery varies depending on the subcellular location of the misfolding lesion in the protein. For example, integral membrane proteins can expose misfolded domains on the cytosolic side of the membrane, within the ER membrane, or in the ER lumen. In yeast, the processes that recognize these lesions are referred to as ERAD-C, ERAD-M, and ERAD-L, respectively, and rely on a specific set of chaperones and ubiquitin conjugating enzymes

Figure 4 The yeast Doa10, Hrd1, and Cdc48 complexes, and the 26S proteasome. Schematic diagram of the (a) Doa10, (b) Hrd1, and (c) Cdc48 complexes and the 26S proteasome (please see the text for a description of the relevant components of each complex). The Cdc48 complex (with Ufd1, Npl4, and Ubx2) is a component of both the Doa10 and Hrd1 complexes and is shown in light gray in the background of (a) and (b). Shown in (c) are additional Cdc48 co-factors such as the E4 Ufd2, which lengthens the polyubiquitin chain, Dsk2 and Rad23, which target polyubiquitinated proteins to the proteasome, and the *N*-glycanase Png1. The 26S proteasome is shown, with the two 19S caps and the 20S core.

(Carvalho *et al.*, 2006; Kanehara *et al.*, 2010; Vashist and Ng, 2004; Huyer *et al.*, 2004; Denic *et al.*, 2006; Figure 3(a)). ERAD-C requires cytosolic chaperones and the Doa10 complex, whereas ERAD-L relies on luminal chaperones and requires the Hrd1 complex (Figures 4(a) and 4(b)). ERAD-M is less well understood, and only requires a subset of the Hrd1 complex components. These complexes are located in the ER membrane, and their main function is to ubiquitinate and extract ERAD substrates from the ER lumen (for soluble ERAD-L substrates) or membrane (for ERAD-M or -C substrates). Doa10 and Hrd1 are E3 ubiquitin ligases (see below), and they associate with additional factors that determine their client specificity and function and that aid in substrate extraction from the ER. Common co-factors include the Ubc7 E2 ubiquitin-conjugating enzyme and its membrane-anchoring partner and activator, Cue1 (Bagola *et al.*, 2013; Bazirgan and Hampton, 2008; Biederer *et al.*, 1997; Metzger *et al.*, 2013). The Cdc48 complex is also a common component (Figure 4(c)). The Cdc48 complex contains the cytosolic AAA ATPase Cdc48 (also known as p97 or VCP in mammals), two co-factors Ufd1 and Npl4, and a putative membrane-anchor, Ubx2 (Jarosch *et al.*, 2002; Neuber *et al.*, 2005; Schuberth and Buchberger, 2005; Ye *et al.*, 2003; Figure 4). One unique component in the Doa10 complex is the transmembrane E2 Ubc6 (Swanson *et al.*, 2001; Figure 4(a)). Unique components in the Hrd1 complex are the transmembrane proteins Der1, Usa1, and Hrd3, and the luminal lectin-like protein Yos9 (called Derlin-1, Herp, SEL1L, and OS-9 in mammals, respectively) (Figure 4(b)). These co-factors help in substrate retro-translocation (Der1) (Mehnert *et al.*, 2013; Greenblatt *et al.*, 2011), regulate Hrd1 activity (Usa1 and Hrd3) (Carroll and Hampton, 2010; Horn *et al.*, 2009; Kostova *et al.*, 2007;

Okuda-Shimizu and Hendershot, 2007), or are part of a dual recognition system for both glycosylated and unglycosylated ERAD substrates (Hrd3, Yos9, and Usa1) (Benitez *et al.*, 2011; Gauss *et al.*, 2006; Quan *et al.*, 2008; Stanley *et al.*, 2011). Hrd3 interacts with Yos9 and indirectly with BiP (through Yos9) and can therefore be considered a receptor for ERAD-L substrates. Although the core machinery is conserved from yeast to mammals, it is more difficult to distinguish ERAD-L, ERAD-C, and ERAD-M in mammalian cells (Vembar and Brodsky, 2008; Bernasconi *et al.*, 2010).

The fatty and sweet sides of destruction

What is the minimal signal that a misfolded protein needs to display for ERAD? As described above, the recognition of misfolded proteins in the lumen or even on the cytosolic side of the ER (for ERAD-C substrates) occurs through exposed hydrophobic stretches that would normally be buried in the native structure. These stretches are bound by chaperones. Prolonged chaperone interaction leads to ERAD targeting, potentially by bringing substrate and ubiquitin ligases together (Nakatsukasa *et al.*, 2008; Han *et al.*, 2007; Figure 1(g)). In the ER lumen, there is an additional signal for ERAD: the glycan (see above). However, only specific glycans within a substrate are required for ERAD selection, and they require the presence of an adjacent unfolded region, thereby functioning as a bipartite signal (Kostova and Wolf, 2005; Spear and Ng, 2005; Xie *et al.*, 2009).

Although the majority of secretory proteins contain *N*-linked glycans, some ERAD substrates are not glycosylated (Apweiler *et al.*, 1999). How are these proteins targeted for ERAD? Cell-free assays developed using yeast were critical to shed light on some of the required components (McCracken

and Brodsky, 1996; Werner *et al.*, 1996). These studies identified BiP and two BiP-associated Hsp40s as factors required for the ERAD of a non-glycosylated substrate (Brodsky *et al.*, 1999; Nishikawa *et al.*, 2001). Interestingly, Cne1 (CNX in mammals) was also required (McCracken and Brodsky, 1996). In fact, many factors that recognize *N*-linked glycosylated proteins are required for the degradation of unglycosylated substrates, including EDEM2, OS-9/Yos9, XTP3-B, and SEL1L/Hrd3 (Shenkman *et al.*, 2013; Gauss *et al.*, 2006; Cormier *et al.*, 2009; Ihara *et al.*, 1999; Tang *et al.*, 2014). Other lectins, such as EDEM1 and EDEM3, are able to interact with unglycosylated substrates but appear to play no role in their degradation (Tang *et al.*, 2014). In contrast, the yeast EDEM1 homolog, Htm1/Mnl1, does not appear to act on unglycosylated substrates, perhaps because an *N*-terminal substrate binding region is absent in Htm1 (Marin *et al.*, 2012). Similarly, Herp (Usa1 in yeast) is required for the Hrd1-dependent degradation of both glycosylated and unglycosylated substrates. Herp directly associates with Hrd1, Derlin-1, and the proteasome (Okuda-Shimizu and Hendershot, 2007; Schulze *et al.*, 2005; Huang *et al.*, 2013), and acts on CNX-independent but BiP and ERdj5 dependent unglycosylated substrates (Ushioda *et al.*, 2013) (Figure 1(g)). The ability of these lectins to bind to a variety of substrates independently of their glycan content underscores the complexity of the system and the inherent difficulties in dissecting the role these factors play in the degradation of ERAD substrates.

Similar to the mannose timer model for misfolded glycoproteins, the folding of unglycosylated proteins can also time out, at least in yeast. This timing mechanism, termed Unfolded Protein *O*-mannosylation (UPOM), requires an enzymatic reaction that adds a mannose to a Ser or Thr side chain (Xu *et al.*, 2013) (Figure 1(f)). The enzymes required for this reaction are Pmt1 and Pmt2. *O*-mannosylation terminates folding, reduces BiP binding, and helps the misfolded substrate remain soluble for the cytosolic proteasome-mediated degradation (Nakatsukasa *et al.*, 2004). It is unclear whether the folding rate or intrinsic properties of folding intermediates determine when a substrate will become *O*-mannosylated, and further studies are needed to determine the generality of this pathway. Besides playing a role during ERAD, *O*-mannosylation has also been postulated to act upstream of the ERAD decision, helping folding intermediates escape ERAD and remain soluble until they find the subcellular location or binding partner required to attain their native fold (Kleizen and Braakman, 2013).

Molecular chaperones: Critical partners during substrate selection and delivery

Chaperones are intimately involved in the decision of whether or not to degrade a substrate. One of the most important chaperone families involved in ERAD substrate recognition is the family of luminal and cytosolic Hsp70s. BiP/Grp78 (also known as Kar2 in yeast) is the only ER luminal Hsp70, while there are multiple constitutively expressed Hsc70s and stress-inducible cytosolic Hsp70s, especially in higher eukaryotes (Kabani and Martineau, 2008; Kampina and Craig, 2010). BiP binding is not only critical for ERAD-L substrate recognition, but also for maintaining ERAD substrate solubility and delivery to ubiquitin ligases (Nishikawa *et al.*, 2001; Nishikawa *et al.*, 2005). Other chaperones and chaperone-like

proteins that participate in ERAD-L substrate recognition or delivery to the retro-translocation/ubiquitination machinery include the PDIs, OS-9/Yos9, Hrd1, and Herp/Hrd3, and the mammalian CNX, UGGT, Grp94 (an ER Hsp90), and chaperone/disulfide reductase ERdj5 (Christianson *et al.*, 2008). ERAD-M substrates can be directly recognized by Hrd1, obviating the requirement for substrate recognition chaperones (Sato *et al.*, 2009). ERAD-C substrates are recognized and targeted for degradation by cytosolic factors, including Hsp70/Hsc70, Hsp40, Hsp26, and Hsp42 (Huyer *et al.*, 2004; Ahner *et al.*, 2007; Youker *et al.*, 2004). In the absence of chaperone function – and in some diseases (Guerriero and Brodsky, 2012) – ERAD substrates can aggregate and must be eliminated through other pathways. Alternative degradation pathways include autophagy and secretory pathway delivery to the vacuole/lysosome (Kruse *et al.*, 2006; Kario *et al.*, 2011; Kroeger *et al.*, 2009; Johnston *et al.*, 1998; Houck *et al.*, 2014).

Getting Back Out: The Retro-Translocation of Misfolded Substrates

Since the proteasome resides in the cytosol, luminal ERAD substrates must be moved into the cytosol for degradation and integral membrane proteins must be extracted from the lipid bilayer of the ER. This process is called retro-translocation or dislocation, and involves the following events: ER membrane targeting (of soluble substrates), enzymatic modification of the substrate with ubiquitin, and energy-dependent extraction of the substrate from the ER lumen/membrane.

Prior or during retro-translocation, some substrates are unfolded through the action of PDIs or ERdj5 (Tsai *et al.*, 2002; Ushioda *et al.*, 2008; Molinari *et al.*, 2002; Tsai *et al.*, 2001), *N*-glycoproteins are deglycosylated by the cytosolic PNGase enzyme (Png1 in yeast) (Suzuki *et al.*, 2000; Hirsch *et al.*, 2003), and most substrates in yeast are ubiquitinated by Doa10 and Hrd1 (Figures 3 and 4), although mammalian cells have a significantly larger set of ubiquitin ligases. The energy for retro-translocation is usually provided by the ATP hydrolyzing hexameric AAA ATPase, Cdc48 (see above; Wolf and Stolz, 2012; Carlson *et al.*, 2006). The Cdc48 complex binds substrates *en route* to the proteasome and participates in their dislocation (Ye *et al.*, 2003; Elkabatz *et al.*, 2004). However, Cdc48 is not always required for retro-translocation (Kothe *et al.*, 2005). In some cases, the AAA ATPases embedded in the 19S cap of the proteasome can provide the energy for retro-translocation (Lee *et al.*, 2004).

One of the most important questions in the field refers to the identity of the retro-translocation channel. Based on their topologies, soluble and integral membrane proteins present distinct challenges for dislocation. Furthermore, these proteins may contain folded sub-domains and posttranslational modifications like glycosylation or disulfide bridges. Therefore, the putative retro-translocation channel must accommodate bulky structures. In fact, there is evidence that some soluble luminal proteins can be retro-translocated while fully folded (Tirosh *et al.*, 2003; Olzmann *et al.*, 2013). Then, how are misfolded substrates exported to the cytosol? One attractive idea is that the Sec61 translocon may function as the pore. There is one example in which a soluble protein

(Apolipoprotein B) remains associated with Sec61 until either co-translational translocation finishes or retro-translocation occurs (Brodsky and Fisher, 2008). The interaction of Sec61 with ERAD components and the proteasome, and its requirement for the retro-translocation of several substrates further support this idea (Plempner *et al.*, 1999; Scott and Schekman, 2008; Wiertz *et al.*, 1996b; Tretter *et al.*, 2013). However, the small diameter of the pore may preclude the retro-translocation of glycosylated proteins and those that retain native structure (Van den Berg *et al.*, 2004). Other transmembrane proteins have been suggested to act as retro-translocation channels for soluble substrates, including Der1, Hrd1, Doa10, and the mammalian gp78 (Mehnert *et al.*, 2013; Wahlman *et al.*, 2007; Carvalho *et al.*, 2010; Bernardi *et al.*, 2010; Swanson *et al.*, 2001). Supporting a role for Hrd1 as the retro-translocator, recent evidence suggests a model in which luminal substrates traverse the ER membrane by inserting polypeptide loops in the channel formed by the Hrd1 transmembrane domains. Formation of these retro-translocation intermediates depends not only on known ERAD luminal targeting factors (Yos9, Hrd3, and Der1), but also, interestingly, on the function of cytosolic factors (including the Hrd1 ubiquitin ligase activity and the Cdc48 complex) (Carvalho *et al.*, 2010). However, mutations in any of the putative retro-translocation channels prevent the ERAD of specific and some common substrates, but none prevents the retro-translocation of all substrates (Hebert *et al.*, 2010; Swanson *et al.*, 2001). Therefore, retro-translocation channels may be functionally redundant. Alternatively, none of these candidates may reflect the sole exit strategy. Instead, misfolded proteins could exit the ER through, for example, lipid droplets (Ploegh, 2007), although lipid droplet formation appeared dispensable for ERAD in yeast (Olzmann and Kopito, 2011).

The mechanism underlying the retro-translocation of integral membrane proteins is similarly mysterious (Thibault and Ng, 2012; Ismail *et al.*, 2006). Some transmembrane substrates are fully extracted from the membrane in a Cdc48/p97-dependent manner, and this step can be uncoupled from degradation (Nakatsukasa *et al.*, 2008; Garza *et al.*, 2009; Lechner *et al.*, 2009). Other substrates remain membrane-integrated, but proteasome degradation still requires Cdc48/p97 and ubiquitination (Ikeda *et al.*, 2009). The channel – if it exists – that permits membrane protein extraction is unknown. Overall, much work remains to be done to understand the mechanism of substrate retro-translocation.

Signaling for Degradation: the Ubiquitin Mark

Protein ubiquitination occurs when ubiquitin, which is a highly conserved 76-amino acids protein, is covalently attached to a target protein. Ubiquitin is most commonly appended onto the ϵ -amino group of a Lys, forming an isopeptide bond. There are different types of ubiquitination – mono, multi-mono, and polyubiquitination – depending on how many ubiquitins are attached in tandem onto a substrate. Since each ubiquitin contains eight residues onto which additional ubiquitins can be conjugated (7 Lys and the N-terminus), polyubiquitin chains can attain a high degree of structural diversity (Winget and Mayor, 2010). This

complicated code is used to regulate a plethora of cellular activities, including ERAD.

Ubiquitination is the ultimate signal of the ‘quality control code.’ Proteasomal degradation requires a polyubiquitin chain of at least four molecules linked via the C-terminal carboxylate of one ubiquitin and onto a Lys at position 48 in the next molecule (Chau *et al.*, 1989; Flierman *et al.*, 2003). However, the proteasome is promiscuous and can degrade substrates ubiquitinated on other residues (e.g., Cys, Ser, and Thr) or with different chain types, and even those that are not ubiquitinated (Kravtsova-Ivantsiv and Ciechanover, 2012). Substrate ubiquitination requires the concerted action of three enzymes: a ubiquitin-activating enzyme (E1), a ubiquitin conjugating enzyme (E2), and a ubiquitin ligase (E3) (Figure 3(c)). There are also ubiquitin-chain-extension enzymes (E4) (e.g., Ufd2) that play a role in the ERAD of some substrates (Richly *et al.*, 2005; Nakatsukasa *et al.*, 2008; Figure 4(c)). The substrate specificity of the ubiquitination reaction is achieved through the combination of the function of the E2s, E3s, and other factors, such as chaperones (Christianson and Ye, 2014). As described above, the Doa10 and Hrd1 E3 ligases are required for the ERAD of most substrates in yeast. Both of these are RING finger E3 ligases, and bring substrates in proximity to ubiquitin-conjugated E2s (Swanson *et al.*, 2001; Bays *et al.*, 2001; Deak and Wolf, 2001). In turn, the E2 receives ubiquitin from the E1. Yeast E2s implicated in ERAD include Ubc7, Ubc6, and Ubc1 (McGrath *et al.*, 1991; Kostova *et al.*, 2007). ERAD can occasionally occur in the absence of Doa10 and Hrd1 function, and in this case other membrane-bound or cytosolic E3s (Ubr1 and Rsp5) function instead or contribute to degradation (Stolz *et al.*, 2013; Haynes *et al.*, 2002). In mammals, there is a considerably larger number of ERAD-associated E3s, including the ER residents Synoviolin/HsHrd1, TEB4, and gp78, and the cytosolic proteins Parkin and CHIP (Kostova *et al.*, 2007; Claessen *et al.*, 2012). Substrates can be ubiquitinated by multiple E3s, which act redundantly, simultaneously, or sequentially. E3s also self-ubiquitinate and ubiquitinate each other, a process that may fine tune ERAD (Olzmann *et al.*, 2013; Bernasconi *et al.*, 2013). Interestingly, the ubiquitination machinery and de-ubiquitinating enzymes also regulate the retro-translocation and degradation of non-ubiquitinated substrates, probably by acting on the ERAD machinery (Bernardi *et al.*, 2013). Thus, protein ubiquitination is a complex but universal signal for degradation that directly and indirectly impacts the fate of ERAD substrates.

At the End, the Proteasome

ERAD substrate elimination requires the 26S proteasome, which is a large (~2500 kDa), multimeric complex. The 26S proteasome is composed of a core, the 20S particle where proteins are degraded by unique ATP-dependent proteases, and the ‘caps,’ which are 19S regulatory particles that participate in substrate selection, de-ubiquitination, and unfolding (Schmidt and Finley, 2013; Figure 4(c)). Due to the presence of the 19S cap, entrance to the core is regulated, which prevents indiscriminate protein degradation in the cell. AAA+ ATPases located at the base of the caps regulate and drive substrate delivery into the 20S core (Smith *et al.*, 2007).

Nearly all ERAD substrates require the Cdc48 complex for delivery to the proteasome. In yeast, Cdc48 may hand substrates over to the proteasome via two adapter proteins, Rad23 and Dsk2 (Chen and Madura, 2002; Figure 4(c)), although Cdc48 also binds the proteasome (Barthelme and Sauer, 2012; Verma *et al.*, 2000). However, the proteasome itself binds ubiquitinated substrates by virtue of 19S-associated receptors, and can interact with the Hrd1 complex in the absence of functional Cdc48 (Nakatsukasa *et al.*, 2013). Further, there exists a proteasome subpopulation already localized at the ER membrane, which may be dedicated for ERAD (Palmer *et al.*, 1996). Therefore, coupling factors that act as intermediaries between Cdc48 and the proteasome may be dispensable for the degradation of at least some ERAD substrates. Prior to entry into the 20S core, ubiquitin is stripped from the substrate through the action of proteasome-associated deubiquitinases (Figure 3(d)). This process is required for delivery of the substrate into the 20S core chamber and is also critical to recycle ubiquitin (Smith *et al.*, 2007).

Concluding Remarks

Maintaining proteostasis is critical for cell survival. Since the discovery of the secretory pathway, a surprisingly large number of complex and interconnected cellular processes have been identified that help facilitate the quality control and the traffic of secretory proteins. Some of these processes, very recently uncovered, include quality control processes that occur in the cytosol, such as prERAD and the activity of surveying factors for mis-targeted TA proteins (Ast *et al.*, 2014; Okreglak and Walter, 2014), as well as quality control processes that occur at the ER, such as selective autophagy and ERQC autophagy (Houck *et al.*, 2014; Park *et al.*, 2014). Intense research in these areas will surely bring to light numerous novel exciting pieces to complete the protein quality control puzzle.

Even after more than two decades since ERAD was discovered many fundamental questions remain unanswered: How does the molecular machinery 'decide' on the folding status of a protein? How are the different aspects of the 'quality control code' decoded by the chaperones and lectins? Which proteins form the retro-translocation channel? How are transmembrane proteins dislocated and degraded? Furthermore, several microbes require the ERAD machinery in the host cell for pathogenesis (Loureiro and Ploegh, 2006; Cho *et al.*, 2012; Eshraghi *et al.*, 2014; Noack *et al.*, 2014). How do they co-opt the ERAD machinery and for what specific purpose? Importantly, much needs to be learnt about how ERAD and the cellular proteostasis network communicate, how these interactions change during disease or aging, and how we may modulate distinct nodes in the network to treat the expanding number of human diseases linked to the ERAD pathway.

Glossary

Cathepsins A group of cysteine, aspartic, and serine peptidases with broad substrate specificity that enables complete degradation of their substrates. In addition, their function can also be more specific, for example, in the immune response.

CLEAR gene network A network of genes coding for various lysosomal proteins with a specific CLEAR sequence and regulated by transcription factor EB.

Lysosomal storage disorders A group of almost 60 genetic diseases caused by deficiencies in genes coding for proteins of the lysosomal system.

Lysosome-related organelles Cell-type specific group of organelles biogenetically similar to lysosomes.

Lysosomes Highly dynamic acidic organelles responsible for degradation of various intra- and extracellular material.

Introduction

Cells are equipped with two major systems for intracellular protein degradation, the ubiquitin-proteasome system and the endolysosomal system (Turk *et al.*, 2012a). The ubiquitin-proteasome system is the major machinery for recycling of short-lived proteins, for degradation of misfolded or damaged proteins within the nucleus and the cytoplasm, thereby representing the quality control of the cell, as well as for the processing of cytosolic antigens for antigen presentation (Kleiger and Mayor, 2014; Blum *et al.*, 2013). On the other hand, the endolysosomal system is responsible for nonspecific degradation of bulk material and organelles to retain energy homeostasis, for processing of exogenous antigens for major histocompatibility complex class II (MHC-II)-mediated immune response, for bone resorption, and processing of other proteins including hormones. In addition, lysosomal proteases are involved in numerous extralysosomal processes in health and disease, including in extracellular protein processing and degradation in various pathological processes (Turk and Turk, 2009; Turk *et al.*, 2012b). In this article the focus will be on the endolysosomal system.

Lysosomes are highly dynamic compartments limited by single-phospholipid bilayer and are found in nearly all eukaryotic cells. They were first described by Christian de Duve and coworkers back in the mid-1950s, a discovery that was awarded with a Nobel Prize for medicine and physiology (de Duve, 1959). They are morphologically heterogeneous, varying from globular to tubular shape with electron-dense interior. Their main characteristics are highly acidic lumen (pH 4.5–5.0) and the absence of mannose-6-phosphate receptor (M6PR), which distinguish them from other less acidic organelles of endocytic pathway, such as early endosomes (EEs) and late endosomes (LEs) or hybrid organelles (Saftig and Klumperman, 2009).

Lysosomes represent the terminal degradative compartments that receive and degrade material from endocytic, phagocytic, and autophagic pathways, providing building

blocks for synthesis of new macromolecules. During the years a lot has been learned about their function. It is now clear that their role is not limited to degradation of bulk material, and that they are also involved in diverse cellular processes like membrane repair, pathogen defense, antigen presentation, cell death, and cell signaling (Figure 1; Luzio *et al.*, 2007; Saftig and Klumperman, 2009; van Kasteren and Overkleeft, 2014). Recently, lysosomes have also been found to have an important role in the regulation of energy metabolism through sensing nutrient availability and activating lysosome-to-nucleus signaling pathway that mediates the starvation response (Settembre *et al.*, 2013). In certain cells, particularly of hematopoietic origin and in melanocytes, the lysosomal catabolic function is complemented with lysosome-related organelles (LROs) or secretory lysosomes, which are biogenetically similar to lysosomes. The best characterized LROs are melanosomes, lytic granules, azurophilic granules, and MHC-II compartments from dendritic cells (Dell'Angelica *et al.*, 2000; Saftig and Klumperman, 2009).

Lysosomes as well as LROs are considered as important regulators of cellular well-being and homeostasis and any abnormality that affects their proper function or turnover can lead to various diseases. Classic examples of the diseases of the lysosomal system are lysosomal storage disorders (LSDs). LSDs are a group of nearly 60, mostly rare genetic diseases and are caused by mutations or deficiencies in genes coding for various lysosomal proteins, which result in accumulation of nondegraded material within the lysosome (Schroder *et al.*, 2010; Schultz *et al.*, 2011). One of the first LSDs was described by Pompe in the early 1930s. It is associated with impaired glycogen degradation, and interestingly, it was this discovery that helped to facilitate the later discovery of the lysosome (Pompe, 1932; Parkinson-Lawrence *et al.*, 2010; de Duve, 1959). The connection between lysosomes and LROs has also been highlighted by studies on multiorganellar genetic LSDs such as Hermansky-Pudlak and Chediak-Higashi syndromes (Dell'Angelica *et al.*, 2000). In addition to LSDs, deregulation of function of lysosomal proteins, such as their increased

Figure 1 Major functions of lysosome and lysosomal hydrolases in intracellular degradation. Lysosome and lysosomal hydrolases, especially the cathepsins, are involved in numerous cellular processes. They are indispensable in the endocytic and phagocytic pathways, where they degrade various extracellular materials, from fluids and macromolecules to microbial organisms and apoptotic cells. Moreover, lysosomes are involved in the turnover of intracellular material, such as organelles and macromolecules in the process of macroautophagy. In another type of autophagy, CMA, lysosomal proteases degrade cytosolic proteins with a specific amino acid sequence motif, based on which they are transported directly into the lysosomes through the LAMP-2A, which serves as a receptor for proteins destined for CMA-mediated degradation. Lysosomes are important also for plasma membrane repair, which is mediated by the process of lysosomal exocytosis. Lysosomal proteases and lysosomal membrane proteins are also essential in the adaptive immune response, where they are involved in major histocompatibility complex class II (MHC-II)-dependent antigen presentation. However, when the membrane of lysosomes and LEs is permeabilized (LMP) then the released hydrolases, particularly cathepsins, can induce apoptosis, necrosis, or pyroptosis, depending on the cell type and the extent of endosome and lysosome rupture.

expression, combined with their improper localization and/or secretion, is also linked to numerous widespread diseases, including cancer, atherosclerosis, late onset neurodegenerative diseases, rheumatoid arthritis, inflammatory bowel disease, and others (Appelqvist *et al.*, 2013; Maxfield, 2014; Vasiljeva *et al.*, 2007; Reiser *et al.*, 2010).

Lysosomal Proteins

Soluble Hydrolases

As primary catabolic organelles, lysosomes exert their function through nearly 60 different soluble acid-dependent hydrolases such as proteases, phosphatases, nucleases, glycosidases, sulphatases, lipases, and others, which collectively perform degradation of various intra- and extracellular material like sphingolipids, glycogen, glycosaminoglycans, and proteins.

Among the enzymes, proteases have a major role, especially the cathepsins. In addition, several lipases have important roles, such as acid sphingomyelinase (ASMase), acid ceramidase, acid lipase, acid or lysosomal phospholipase A₂ (LPLA₂), as well as several glycosidases including α -galactosidase A, β -glucuronidase, α -iduronidase, glucocerebrosidase, and α -galactosidase (Schroder *et al.*, 2010).

Cathepsins

The name cathepsin originates from Greek word 'kathapsein' which means to digest. Cathepsins are divided into three groups based on the amino acid present in the active site: cysteine (in humans we can find cathepsin B, C, or dipeptidyl peptidase I, F, H, K, L, O, S, V, W, and X), aspartic (D and E), and serine cathepsins (A and G). The majority of them can be found in most living organisms and ubiquitously expressed

Figure 2 Fold of mature cathepsin L, a typical cysteine cathepsin endopeptidase. The fold of the two-chain form of native cathepsin L (1icf) is shown in the ribbon representation with heavy chain in light blue and light chain in dark blue. The side chains of the active-site cysteine (Cys25) and histidine (His163) residues, each residing on one side of the active site cleft, are indicated in a ball-and-stick representation.

among different tissues. However, some of them are cell-type specific, such as cathepsin K or cathepsin S and W, which are mainly found in osteoclasts or in specific immune cells, respectively. Likewise, cathepsin V is expressed predominantly in the thymus and testicles, and cathepsin G is found only in the azurophilic granules in neutrophils. The cell-type specific localization suggests a more specific role for the cathepsins in these cells. Furthermore, the members of the cysteine group and the aspartic cathepsin D are found throughout the endolysosomal system, whereas the aspartic cathepsin E is found only in the endosomes (Repnik *et al.*, 2012; Turk *et al.*, 2012b).

Cysteine cathepsins belong to the clan CA of cysteine peptidases, more specifically to the C1 family of papain-like enzymes, the largest and, in addition to the aspartic cathepsin D, the most studied group of lysosomal proteases. Cysteine cathepsins are predominantly endopeptidases (Figure 2), with the exception of cathepsins B and H, which are endo- as well as exopeptidases, and cathepsin X and C, which are strictly exopeptidases. Exopeptidase activities of these cathepsins are consequences of different structural elements, such as the occluding loop and mini loop in carboxypeptidases cathepsins B and X, respectively, and the remaining parts of their proregions such as seen in aminopeptidases cathepsins H and C, which protrude in the active site cleft, thereby sterically hindering substrate binding (Turk *et al.*, 2012a). Moreover, cysteine cathepsins exhibit broad substrate specificity, which combined with their endo- and exopeptidase activities ensures complete degradation of their substrates (Turk *et al.*, 2012b). Nevertheless, cathepsins can also have more specific functions within lysosomes or LROs, such as found for cathepsin C, which has a major role in processing of numerous other granule proteases, including granzymes A and B, neutrophil elastase, cathepsin G, and chymase (Turk *et al.*, 2001).

In order to be optimally active, lysosomal hydrolases, including cathepsins, require a reducing, slightly acidic

environment, such as found in the endolysosomal system. The acidic pH and reducing conditions in the endolysosomal system are not only optimal for cathepsin activity and stability, but also help in loosening the structure of macromolecules, which increases the number of potential cleavage sites, thereby facilitating their degradation. Because of their enormous degradative potential, their action has to be well regulated and, importantly, confined to the acidic vesicles. The first and essential barrier that separates the acidic interior-rich hydrolases from the rest of the cell is the 7–10 nm thick lysosomal membrane, which is well protected against degradation by heavily glycosylated luminal domains of membrane proteins that form a thick glycocalyx (Granger *et al.*, 1990). Secondly, all cathepsins are synthesized as inactive precursors, which can be largely activated only in the acidic environment of the endolysosomal system. Their activation can be autocatalytic or catalyzed by other proteases, including cathepsin D, and can be largely facilitated by glycosaminoglycans. Moreover, cysteine cathepsins are relatively unstable at neutral pH due to irreversible unfolding, which provides another level of protection. The exception is cathepsin S, which remains active for several hours at neutral pH. Particularly sensitive to neutral pH are the aspartic cathepsins because of the reversible deprotonation of Asp residues in the active site. Nevertheless, their limited activity at neutral pH, such as found within the cytosol or in the extracellular milieu seems to be sufficient for substrate cleavage and thus proteolytic signaling even under such unfavorable conditions, which can be very harmful and can have devastating consequences (Repnik *et al.*, 2012; Turk *et al.*, 2012b; Fonović and Turk, 2014). A major level of control of such escaped cathepsins is provided by their endogenous inhibitors present in the cytosol or extracellularly, such as stefins A and B, certain serpins, or cystatin C (Turk *et al.*, 2002, 2012b).

Cathepsins in the Immune Response

Although cathepsins were long believed to participate exclusively in nonspecific protein degradation, it is now clear that the concept of ‘regulation through limited destruction’ takes part in various physiological processes, in particular in the immune response. Especially well characterized is their role in MHC-II antigen processing and presentation, although they are implicated also in cytokine regulation, natural killer T cell development, and other processes (Colbert *et al.*, 2009).

In the adaptive immune response foreign antigens are internalized either through endocytosis or phagocytosis and degraded into peptides, which are recruited to the MHC-II molecules that present them to the CD4⁺ T-helper cells on the cell surface. In comparison to MHC-I molecules, which bind peptides generated by the proteasome system in the endoplasmic reticulum (ER), MHC-II molecules mostly bind peptides generated by endolysosomal proteolysis. Contrary to antigen processing, which is generally nonspecific process with a great amount of redundancy, processing of the MHC-II invariant chain is a highly controlled and coordinated process. MHC-II molecules are assembled within the ER, whereas the maturation occurs in endosomal compartments, which are rich with antigenic peptides. MHC-II molecules consist of

α and β subunits, and the invariant chain (Ii), responsible for assembly of the MHC-II complex and targeting it to LEs, which occurs either through trans-Golgi network (TGN) or endocytosis. Due to alternative splicing, several forms of Ii exist, and the longest, the p41 Ii variant, possesses a glycosylated domain, which was shown to inhibit cathepsin L and thereby regulate its activity in antigen presentation. Processing of MHC-II invariant chain occurs through several consecutive C-terminal cleavages that culminate in a variably extended peptide of approximately 20 residues called CLIP (class II-associated invariant chain peptide). Multiple cathepsins have been shown to be involved in the Ii processing; however, their function seems to be cell-type specific. In dendritic and B cells cathepsin S was thus found to play a crucial role in the final stages of processing, while in cortical thymic epithelial cells cathepsin L (V in humans) perform the processing. The CLIP–MHC-II complex is then, at least in humans, recognized by the human leukocyte antigen (HLA)-DM chaperone that is highly homologous to the MHC-II molecule and facilitates the substitution of the CLIP fragment with the antigenic peptides and its subsequent presentation to the CD4⁺ T-helper cells (Blum *et al.*, 2013; Cresswell, 1996; Turk *et al.*, 2012a).

In addition to immune response, cathepsins participate also in bone remodeling, keratinocyte differentiation, and prohormone activation for neuropeptide biosynthesis (Turk *et al.*, 2012b). They can also be found within the nucleus, where they regulate cell cycle (Duncan *et al.*, 2008), as well as in the extracellular space, where they participate in numerous physiological processes like bone remodeling and wound healing (Fonović and Turk, 2014).

However, excessive cathepsin activity is often associated with diseases. In most of these diseases, cathepsins are secreted into the extracellular milieu, often from the immune cells infiltrated to the disease site and therefore represent markers for numerous inflammation-associated diseases, including cancer, rheumatoid arthritis and osteoarthritis, atherosclerosis, and inflammatory bowel diseases. In addition, cathepsin K has a major role in osteoporosis. Therefore, cathepsins represent important targets for drug development and drugs targeting cathepsin K have successfully finished Phase III clinical trials for osteoporosis treatment (Vasiljeva *et al.*, 2007; Reiser *et al.*, 2010; Fonović and Turk, 2014).

Lysosomes and Lysosomal Cathepsins in Cell Death

The deadly potential of lysosomes was first noticed by Christian de Duve, who referred to lysosomes as ‘suicide bags’ (de Duve, 1959), but it was long after this discovery that the first cytosolic targets of cysteine cathepsins and the mechanism of lysosomal apoptotic pathway were revealed (Blomgran *et al.*, 2007; Cirman *et al.*, 2004; Droga-Mazovec *et al.*, 2008; Stoka *et al.*, 2001). In healthy cells, lysosomal cathepsins normally reside inside the acidic environment of endosomes and lysosomes, which prevents the undesired proteolysis. However, when their membrane is damaged and the inhibitors in the cytosol fail to inactivate the released cathepsins, then they are fatal for the cell and induce apoptosis, necrosis, or pyroptosis, depending on the cell type and the extent of endosome and lysosome rupture (Repnik *et al.*, 2014).

Cysteine cathepsins have the potential to trigger lysosomal apoptosis if the lysosomal membrane is directly damaged, or, alternatively, they can amplify the death signal if apoptosis is initiated outside the endocytic compartment as often seen in late stages of the process (Repnik *et al.*, 2012). One group of compounds that directly target lysosomal membrane are lysosomotropic detergents, which are lipophilic bases that accumulate in acidic vesicles, namely endosomes, lysosomes, and hybrid organelles, where after protonation they become trapped and develop membranolytic properties, which results in the release of the cathepsins into the cytosol (de Duve *et al.*, 1974; Miller *et al.*, 1983). Although the name suggests that lysosomotropic detergents target only lysosomes, they actually affect all acidic vesicles in the cell, i.e., the vesicles of the late endocytic pathway, including LEs, lysosomes, and hybrid organelles. The best example of a lysosomotropic detergent is the dipeptidyl ester LeuLeuOMe, which gains detergent-like properties after polymerization with cathepsin C (Thiele and Lipsky, 1990). LeuLeuOMe studies represent the basis on which the mechanism of lysosomal apoptotic pathway has been determined (Cirman *et al.*, 2004; Droga-Mazovec *et al.*, 2008; Stoka *et al.*, 2001; Uchimoto *et al.*, 1999). The crucial event in lysosomal apoptotic pathway is lysosomal membrane permeabilization (LMP) that enables the release of hydrolases into the cytosol, where they perform rather specific proapoptotic cleavages that trigger a signaling cascade ending with cell death. Cysteine cathepsins (Cirman *et al.*, 2004; Stoka *et al.*, 2001) and aspartic cathepsin D (Appelqvist *et al.*, 2012) have been shown to be the most important lysosomal proteases in the processing of the proapoptotic Bid protein, thereby generating the proapoptotic p15 tBid form (Repnik *et al.*, 2012). tBid is involved in oligomerization of proapoptotic Bak and Bax proteins, which form pores in the outer mitochondrial membrane and thereby release cytochrome *c* into the cytosol. This is also the stage where the lysosomal apoptotic pathway merges with the classical intrinsic apoptotic pathway. In the cytosol, cytochrome *c* and apoptotic protease-activating factor (Apaf-1) form the initiator caspase-9-activating platform named apoptosome. Activated caspase-9 can then proteolytically activate executioner caspase -3, -6 and -7, leading to execution of cell death (Repnik *et al.*, 2014). In addition to Bid activation, cysteine cathepsins also degrade antiapoptotic Bcl-2 molecules and X-chromosome-linked inhibitor of apoptosis (XIAP), thereby facilitating apoptotic cell death (Droga-Mazovec *et al.*, 2008). In addition, other LMP-mediated cell death pathways have been described, but the mechanisms are less clear (Kirkegaard and Jaattela, 2009; Aits and Jaattela, 2013).

Lipases

Among the lipids, best described are sphingolipids, which are involved in a variety of cellular processes, such as cell proliferation, senescence, differentiation, and apoptosis, so their cellular levels must be tightly regulated, which is achieved by a coordinated action of several specific lipases. For example, elevated activity of ASMase and acid ceramidase that convert sphingolipid sphingomyelin to ceramide and sphingosine, respectively, can influence lysosomal membrane stability and

may lead to cell death (Kågedal *et al.*, 2001). Recently, an additional function for ASMase in lysosomal function has been revealed, suggesting that ASMase deficiency impairs autophagy-lysosomal degradation pathway and increases lysosomal cholesterol that in turn increases lysosomal membrane stability (Fucho *et al.*, 2014). On the other hand, inherited mutations in ASMase cause accumulation of sphingomyelin in lysosomes, a condition called Niemann–Pick disease types A and B (Stern, 2014). Furthermore, acid lipase, essential for hydrolysis of cholesterol esters and triglycerides, has also recently been shown to be indispensable for the alternative activation of macrophages after parasite infection (Huang *et al.*, 2014), whereas the genetic deficiency in the enzyme results in autosomal recessive disorders like Wolman disease and cholesteryl ester storage disease (Porto, 2014). Another well-known lipase is LPLA₂, which has a ubiquitous role in lysosomal phospholipid degradation. Negatively charged glycerophospholipids, particularly bis (monoacylglycero)phosphate (BMP), have been found to significantly augment the LPLA₂ activity and to work as a platform for the lipid–water interfacial reaction of lysosomal lipolytic enzymes in intra-endosomal and intra-lysosomal membranes (Shayman *et al.*, 2011). Until now, no defined syndrome has been linked to LPLA₂ deficiency; however, the likelihood that the loss of the enzyme activity causes a disease is very high. Several drugs have been shown to cause a toxic condition, so-called cellular phospholipidosis, as a result of impaired degradation of phospholipids. Such drugs are called cationic amphiphilic drugs (CAD), because they contain an aromatic group and an amine that is protonated under acidic conditions. Despite the importance of the condition, the molecular mechanism that induces it and its pathological consequences at the cell and organ levels still remain unclear (Shayman *et al.*, 2011).

Glycosidases

In addition to proteases and lipases, glycosidases are indispensable for normal lysosomal function. They are responsible for the turnover of numerous endocytosed glycosphingolipids, like ceramides with variable oligosaccharide moieties, which are ubiquitously expressed on the cell surface. Two inherited prototypical glycosphingolipidoses, namely Gaucher and Fabry diseases, which were first already described in the nineteenth century (Ferraz *et al.*, 2014), further stress this importance. The diseases are caused by deficiencies in glucocerebrosidase and α -galactosidase A, respectively, and occur with a prevalence of 1:40 000–100 000. Interestingly, Gaucher disease is even more abundant in Ashkenazi Jewish population, where it occurs with a frequency of 1:900 (Cassinerio *et al.*, 2014). The diseases are classic examples of LSDs, where the non-hydrolyzed substrate, glucosylceramide (glucocerebroside) or globotriaosylceramide, accumulates within the lysosome (Ferraz *et al.*, 2014). Similarly, deficiency in the *N*-acetylglucosamine-1-phosphotransferase, responsible for synthesis of the mannose-6-phosphate (M6P) hydrolase targeting signal for lysosomes, results in mucopolisaccharidosis II and III, as a consequence of improper localization of the enzyme (Idol *et al.*, 2014).

Lysosomal Membrane Proteins

More than 120 different lysosomal membrane proteins are needed to mediate numerous functions of the lysosomal membrane. Among them the best characterized is a transmembrane multiprotein complex, vacuolar H⁺-ATPase, responsible for the acidification of the organelle's interior by using the energy derived from ATP hydrolysis to transport protons across the lysosomal membrane. In addition, there is a complex machinery of membrane proteins responsible for protein import and export from and to the cytosol, as well as proteins for lysosomal trafficking and fusion, which are mediated by a machinery of membrane-associated RAB GTPases and SNARE (SNAP (Soluble NSF Attachment Protein) REceptor) proteins. Especially important lysosomal membrane structural proteins are the so-called lysosome-associated membrane proteins (LAMPs), which regulate macroautophagy, chaperone-mediated autophagy (CMA), and direct lysosomal transport for cytosolic proteins (Ruivo *et al.*, 2009; Saftig and Klumperman, 2009). Recently, it has been shown that LAMPs regulate also the positioning of lysosomes and mitochondria, which subsequently affects the energy metabolism (Rajapakshe *et al.*, 2014). The most abundant structural protein is LAMP-1, which accounts for 50% of the total protein in the membrane (Settembre *et al.*, 2013). Deficiency in another LAMP, LAMP-2A (lysosome-associated membrane protein 2A), is known to cause Danon disease, an X-linked lysosomal disease, associated with the accumulation of autophagic vacuoles in muscle cells, resulting in cardiomyopathy, skeletal myopathy, and mental retardation. Interestingly, until now more than 60 different mutations have been found in the LAMP-2 protein only (Cheng and Fang, 2012). A mutation of another lysosomal protein Niemann–Pick C1 protein 1, involved in the export of cholesterol from the endolysosomal compartment, results in an autosomal recessive lipid storage disorder, namely Niemann–Pick disease type C, characterized by progressive neurodegeneration. Another mutation in the lysosomal membrane protein called heparin- α glucosaminide *N*-acetyltransferase impairs the stepwise degradation of heparin sulfate, resulting in mucopolysaccharidosis type IIIC (Settembre *et al.*, 2013). These and many other disease-causing mutations illustrate the importance of lysosomal membrane proteins in addition to soluble lysosomal hydrolases.

Lysosomal Biogenesis and Its Regulation

Biogenesis of lysosomal soluble and membrane proteins requires interactions between the biosynthetic and endocytic pathways. Proteins are synthesized in the ER and then transported to the TGN, from where they are targeted to the lysosome in a signal-dependent manner either directly from the TGN or indirectly through the secretory pathway to the plasma membrane and subsequent endocytosis into the cell. The majority of the lysosomal hydrolases are modified with M6P and in the TGN selected by means of M6PR for transport to endosomes (Bräulke and Bonifacino, 2009). For example, cathepsins are synthesized as inactive zymogens (pre-pro-enzymes), which are following the co-translational removal of the pre-peptide and posttranslational glycosylation in the

Golgi apparatus directed toward endosomes, where the zymogens are activated. The acidic environment of the endosome enables dissociation of the M6PR from the hydrolase. The cathepsins are then transferred to lysosomes either through endosome–lysosome fusion or through endosome maturation (Katunuma, 2010). Other soluble hydrolases and nonenzyme proteins are transferred to lysosomes independently of M6PR by alternative transport receptors, such as sortilin as a receptor for prosaposin and ASMase or lysosomal integral membrane protein LIMP-2 as a receptor for β -glucocerebrosidase (Schroder *et al.*, 2010). Compared to the soluble lysosome hydrolases, much less is known about the transport of lysosomal membrane proteins to the lysosome. They contain specific sorting sequences in the cytoplasmic part of the protein known as tyrosine- and dileucine-based motifs responsible for binding of different adaptor protein complexes, which initiate packaging in clathrin-coated vesicles (Braulke and Bonifacino, 2009; Schroder *et al.*, 2010).

A few years ago, a specific gene network, so-called coordinated lysosomal expression and regulation (CLEAR), has been discovered and many genes coding for the lysosomal proteins have been found to contain the CLEAR sequence (GTCACGTGAC). The CLEAR gene network and its master regulator transcription factor EB (TFEB) are crucial regulators of lysosomal biogenesis and function, showing that lysosomal function can be globally controlled (Sardiello *et al.*, 2009). Furthermore, it has been shown that lysosomal function can be coordinated also as a consequence of environmental stimuli. For example, upon starvation TFEB enters the nucleus and binds to CLEAR elements and triggers the transcription of genes important for autophagy as well as for lysosomal biogenesis (Settembre *et al.*, 2013). In addition, non-lysosomal proteins that regulate the functions of lysosome-resident proteins, such as cation-dependent (CD-M6PR) and cation-independent M6PR (CI-M6PR) are of major importance. These proteins circle between TGN and LEs and are responsible for targeting of lysosomal hydrolases to the lysosome (Settembre *et al.*, 2013).

Pathways to the Lysosome

Endocytosis

Extracellular material reaches the lysosomes mostly through the endocytic machinery. Cells have developed several mechanisms of endocytosis, such as phagocytosis, macropinocytosis, clathrin-dependent and clathrin-independent endocytosis, calveolae or calveolin-mediated endocytosis, depending on the physical and chemical nature of the cargo. In general, particles larger than 500 nm enter the cell via phagocytosis or macropinocytosis, whereas smaller material is internalized via other endocytic mechanisms. The best characterized are receptor-mediated clathrin-dependent endocytosis, which dominates and defines the paradigm for endocytic pathway, and phagocytosis, which is important for intake of microbial organisms, apoptotic cells, and cellular debris (Doherty and McMahon, 2009; Kumari *et al.*, 2010).

The process of endocytosis starts on the cell surface where cells internalize fluids, macromolecules, plasma membrane

components, and other particles by invagination of the plasma membrane. The cargo then passes through different endosomal vesicles and vacuoles, so-called endosomal intermediates, through membrane fission until it reaches the final destination, the lysosome (Huotari and Helenius, 2011). An important hallmark of the pathway is the progressive decrease of the luminal pH from EEs (pH ~6) and LEs (pH 5.0–6.0) to lysosomes (pH 4.5–5.0), which is optimal for the activity of hydrolytic enzymes (Saftig and Klumperman, 2009; Turk and Turk, 2009).

The recipients of the incoming cargo from the cellular surface are EEs, which represent the main sorting station of the endocytic pathway. In the EEs the majority of the internalized cargo, such as plasma membrane components and their ligands, is recycled back to the cell surface, the process important for regulation of the cell-surface expression of membrane proteins. The cargo that is not recycled to the cell surface is carried in EEs further along the endocytic pathway to the LEs and finally to the lysosomes either for degradation or for lysosomal biogenesis. Interestingly, a relatively small fraction of internalized material actually reaches the lysosomes due to a stringent selection in the EEs and later in LEs, allowing only a specific cargo to be transported and degraded in the lysosomes. In addition, EEs receive the cargo through bidirectional vesicle exchange with TGN, such as M6PR bound to newly synthesized lysosomal hydrolases, for transport to LEs and lysosomes. In the slightly acidic EEs, M6PR dissociate from the hydrolases and return back to the TGN. In addition, this transport is important for removal of the used components during endosome maturation and also occurs between TGN and maturing LEs, but seldom after the fusion with lysosome. The proteins that enable the bidirectional transport are Rab7, Rab9, and a complex of nexins. An essential component of the membrane of the EE is Rab5 protein, which follows EE through various stages of maturation and is also the major regulator of EE conversion to LE. After the formation in the peripheral cytoplasm, LEs move to the perinuclear region where they undergo transient fusions with other LEs to form larger bodies and eventually fuse with lysosomes or hybrid organelles, called endolysosomes. Finally, by fusing with lysosomes they follow a unidirectional pathway, reaching a point of no return, where some of the components get degraded, whereas the others contribute to lysosomal biogenesis (Huotari and Helenius, 2011; Saftig and Klumperman, 2009).

The endocytic pathway is an extremely dynamic and often elusive process because of the continuous maturation, transformation, fusion, and fission of the organelles. The distinction between the organelles is therefore often difficult, since the majority of proteins are either transiently associated with a certain organelle or they follow it all the way through transformation. Up to now, no specific markers for lysosomes have been identified. LAMPs and acid hydrolases are found both in lysosomes and LEs, however, some proteins, such as cation-independent M6PR, Rab7, and the regulatory (RII) domain of the cAMP-dependent protein kinase, are present only on LEs and therefore enable some discrimination (Repnik *et al.*, 2013).

However, it is worth noting that recent findings suggest that the machinery used for endocytosis is also shared in autophagy, including in regulation of membrane budding and

fusion, role of the lysosome in sensing the nutrient status of the cell, regulation of mammalian target of rapamycin complex 1 (mTORC1) activity, and initiation of autophagy (Lamb *et al.*, 2013). Moreover, there is a dynamic relationship between autophagy and phagocytosis (Oczypok *et al.*, 2013; Vernon and Tang, 2013), including newly discovered autophagic-phagocytosis 'hybrid' processes such as microtubule-associated protein 1 light chain 3-associated phagocytosis (LAP) (Vernon and Tang, 2013). Furthermore, autophagy and phagocytosis share many common features and act in a concerted manner during the clearance of dead cells or autophagy, thus acting as a backup system to fight off infection upon phagocytosis failure to eliminate a pathogen (Eskelinen and Saftig, 2009; Oczypok *et al.*, 2013).

Autophagy

Intracellular material reaches the lysosomes for their degradation through three different types of autophagy, namely, macroautophagy (Eskelinen and Saftig, 2009; Yang and Klionsky, 2010), microautophagy (Mijaljica *et al.*, 2011), and CMA (Wong and Cuervo, 2010; Park and Cuervo, 2013).

(Macro)autophagy is a bulk degradation process that mediates the clearance of macromolecules, damaged organelles, and aggregate-prone proteins (Yang and Klionsky, 2010; Eskelinen and Saftig, 2009; Ravikumar *et al.*, 2010). It is an important survival mechanism that is upregulated upon starvation, oxidative stress, or other harmful conditions. It is initiated by double-membraned structures, which engulf portions of cytoplasm. The magnitude of autophagosome formation is tightly regulated by intracellular and extracellular amino acid concentrations and ATP levels via signaling pathways that include the nutrient-sensing kinase TOR (target of rapamycin). The resulting autophagosomes ultimately fuse with lysosomes, where their contents are degraded. The formation of autophagosomes is tightly regulated by a specific set of autophagy-related (ATG) genes (Yang and Klionsky, 2010; Mizushima *et al.*, 2011). Recently, a systematic proteomic analysis of the autophagy interaction network in human cells under conditions of ongoing (basal) autophagy provided a global view of the mammalian autophagy interaction landscape (Behrends *et al.*, 2010). Interestingly, recent findings suggest that macroautophagy can also occur in the absence of some of these key autophagy proteins through the unconventional biogenesis of canonical autophagosomes (Codogno *et al.*, 2012).

Although autophagy has long been considered to be a nonselective bulk degradation pathway, in the last few years several forms of selective autophagy have been identified, leading to degradation of specific organelles, proteins, and pathogens in yeast, flies, and mammals (Kraft *et al.*, 2009). Two types of cargo selection by autophagy have been described, namely, nonselective and selective autophagy. During the nonselective process, bulk cytosol and other cytoplasmic components are randomly sequestered into autophagosomes, whereas during selective macroautophagy, a specific cargo is exclusively enwrapped into the double-membrane vesicle (Kraft *et al.*, 2009). Selective types of autophagy include the selective degradation of cytoplasmic proteins during bulk autophagy, the Cvt pathway and organellophagy such as mitophagy, pexophagy, reticulophagy, ribophagy, and

piecemeal autophagy of the nucleus (Kraft *et al.*, 2009; Mijaljica *et al.*, 2011; Okamoto, 2014). Moreover, selective types of autophagy only described in higher eukaryotes include aggrephagy, xenophagy, and MHC-II crosspresentation (Johansen and Lamark, 2011; Kraft *et al.*, 2009). Although, all selective types of autophagy use the conserved core autophagy machinery, they also possess a mechanism that assures the accuracy in the specific selection of the cargo that has to be eliminated (Kraft *et al.*, 2009). Available evidence suggests two general mechanisms for cargo recognition. First, a factor on the surface of the cargo molecule might become available to bind an adaptor or receptor, i.e., p62/SQSTM1 and NBR1 that carry out an identical function (Kraft *et al.*, 2009; Johansen and Lamark, 2011). The second principle for selective cargo recognition is the involvement of ubiquitin as a signaling molecule for targeting various types of cargo, ranging from protein aggregates to membrane-bound organelles and microbes (Kirkin *et al.*, 2009; Kraft *et al.*, 2009; Shaid *et al.*, 2013).

The identification of autophagy receptors, such as p62/SQSTM1 and NBR1, which simultaneously bind both ubiquitin and autophagy-specific ubiquitin-like modifiers, LC3 (light chain 3) or GABARAP (gamma-aminobutyric acid receptor-associated protein), has provided a molecular link between ubiquitination and autophagy (Shaid *et al.*, 2013; Kirkin *et al.*, 2009). Although these two systems bear some unique properties, there are a series of essential steps and components common to both of them and required for their functions in cellular quality control. The common steps in protein degradation are cargo selection and tagging, cargo recognition and delivery to the proteolytic machinery, degradation in the proteolytic core, and recycling of the constituent amino acids (Wong and Cuervo, 2010). Moreover, evidence supports different levels of cross talk among autophagic pathways and the ubiquitin-proteasome system where changes in one proteolytic pathway affect other proteolytic systems, components of one proteolytic pathway are degraded by another proteolytic system, and different proteolytic pathways share components and substrates (Park and Cuervo, 2013).

Glossary

Matrix metalloproteinases (MMPs) Endopeptidases secreted from cells or bound to the cell surface and that aid degradation of extracellular matrix molecules.

Metzincins Metalloproteinases that contain the zinc-ion-binding motif HEXXHXXGXXH and a conserved methionine that forms a unique Met-turn structure, for example, matrix metalloproteinases, astacins, repolysins, ADAMs, ADAMTSs, pappalysins, serralysins, and leishmanolysin.

Proteinase Proteolytic enzymes, also known as proteases or endopeptidases that hydrolyze internal peptide bonds of proteins and polypeptide chains (cf. exopeptidase, enzymes that hydrolyze one or a few amino acids from the N- or C-terminus of polypeptides).

Tissue inhibitors of metalloproteinases (TIMP) Tissue inhibitors with molecular masses of 22–30 kDa that inhibit MMPs.

Structure

The matrix metalloproteinases (MMPs) are a subfamily within the M10 family of endopeptidases of the metzincin clan (M10A; Rawlings *et al.*, 2012). They are found in lower eukaryotes and in plants but diversified substantially during the evolution of the vertebrates (Fanjul-Fernandez *et al.*, 2010). In human there are 24 genes, with one gene duplication. A number of the human MMP genes (MMP-1,-3,-7,-8,-10,-12,-13, and -20) are clustered on chromosome 11 at 11q21-23. Other MMP genes are found on chromosomes 1, 8, 12, 14, 16, 20, and 22 (Ugalde *et al.*, 2010). MMPs are multidomain proteinases and their domain structure is

shown in Figure 1. All have a signal peptide, implying that they are secreted proteins. The N-terminal propeptides confer latency and need to be removed by proteolysis to generate the mature enzyme forms (see below). Most MMPs have a catalytic domain linked to a C-terminal hemopexin-like domain by a hinge region, except in the cases of MMP-7, MMP-23, and MMP-26. The 'gelatinases' MMP-2 and MMP-9 have triple fibronectin type II-like repeats inserted into the catalytic domain. The 3D structures of the catalytic domains and some ancillary domains of a number of MMPs have been resolved (Tallant *et al.*, 2010). The MMPs are largely secreted into the extracellular space, however six members are membrane anchored (membrane type, MT MMPs). Four

Figure 1 The domain structure of matrix metalloproteinases.

are transmembrane proteins with short cytoplasmic tails (MT1, MT2, MT3, MT5 MMPs; MMP-14,-15,-16, and -24, respectively) and two have a glycosylphosphatidylinositol (GPI) anchor (MT4, MT6 MMPs; MMP-17 and -25, respectively). MMP-23 is anomalous, containing an N-terminal type II transmembrane region, a cysteine array, and immunoglobulin domains. Although the zinc-containing catalytic domain is responsible for peptide bond hydrolysis, the hemopexin and other extra-catalytic domains, where present, exhibit a range of specific functions from interaction with substrates, TIMPs and pericellular proteins, to regulation of MMP turnover (Murphy and Nagase, 2011; Hadler-Olsen *et al.*, 2011).

Substrate Profiles: Biological and Biomedical Implications

MMPs have been implicated in many biological processes from embryonic development through wound healing, as well as in several pathologies. As secreted enzymes, functional at neutral pH, the mammalian MMPs were originally identified as significant modulators of the extracellular matrix (ECM) in tissue remodeling (Egeblad and Werb, 2002). Alongside proteolytic breakdown of ECM proteins, with a consequent loss in cell interactions, MMP activities can release growth factors bound to the ECM or generate cryptic ligands at specific extracellular protein cleavage sites, with consequent effects on cell

Table 1 Substrates of human matrix metalloproteinases

Enzymes	ECM substrates	Non-ECM substrates
<i>Secreted-type MMP</i>		
Collagenases		
Interstitial collagenase (MMP-1)	Collagens I, II, III, VII, and X, gelatins, aggrecan, link protein, entactin, tenascin, perlecan	
Neutrophil collagenase (MMP-8)	Collagens I, II, and III, gelatins, aggrecan, link protein	α 2-M, α 1-PI, α 1-antichymotrypsin, IGFBP-2, 3, 5, proIL-1 β , CTGF
Collagenase-3 (MMP-13)	Collagens I, II, III, IV, IX, X, and XIV, aggrecan, Fn, tenascin, osteonectin, Ln, perlecan	α 1-PI
Gelatinases		
Gelatinase A (MMP-2)	Gelatins, collagens IV, V, VII, X, and XI, Ln, Fn, elastin, aggrecan, link protein	CTGF, ProTGF- β , MCP-3, α 1-antichymotrypsin
Gelatinase B (MMP-9)	Gelatins, collagens III, IV, and V, aggrecan, elastin, entactin, link protein, vitronectin, N-telopeptide of collagen I	ProTGF- β , FGF receptor I, MCP-3, IGFBP-5, proIL-1 β , galectin-3, plasminogen
Stromelysins		
Stromelysin-1 (MMP-3)	Aggrecan, decorin, gelatins, Fn, Ln, collagens III, IV, IX, and X, tenascin, link protein, perlecan	ProTGF- β , IL-2 receptor α , Kit-L, IGFBP-3, proIL-1 β , ICAM-1, α 1-PI, galectin-3, plasminogen
Stromelysin-2 (MMP-10)	Aggrecan, Fn, Ln, collagens III, IV, and V, link protein	IGFBP-3, proIL-1 β , HB-EGF, CTGF, E-cadherin, α 1-antichymotrypsin, α 1-PI, α 2-M, plasminogen, uPA, proMMP-1, 7, 8, 9, 13
Matrilysins		
Matrilysin-1 (MMP-7)	Aggrecan, gelatins, Fn, Ln, elastin, entactin, collagen IV, tenascin, decorin, link protein	Pro1, 8, 10
Matrilysin-2 (MMP-26)	Gelatin, collagen IV, Fn, fibrinogen, vitronectin	Pro α -defensin, Fas-L, β 4 integrin, E-cadherin, proTNF α , CTGF, HB-EGF
Furin-activated MMP		RANKL, IGFBP-3, plasminogen
Stromelysin-3 (MMP-11)	Fn, Ln, aggrecan, gelatins	ProMMP-9, α 1-PI
Epilysin (MMP-28)	Unknown	α 1-PI, α 2-M, IGFBP-1
<i>Other secreted-type MMP</i>		
Metalloelastase (MMP-12)	Elastin, aggrecan, Fn, collagen IV, osteonectin, Ln, nidogen	Casein
RASI-1 (MMP-19)	Collagen IV, gelatin, Fn, tenascin, aggrecan, COMP, Ln, nidogen	Plasminogen, apolipoprotein(a)
Enamelysin (MMP-20)	Amelogenin, aggrecan, gelatin, COMP	IGFBP-3
MMP-21	Unknown	Unknown
MMP-27	Unknown	Unknown
<i>Membrane-anchored MMP</i>		
Type I transmembrane-type MMP		
MT1-MMP (MMP-14)	Collagens I, II, and III, gelatins, aggrecan, Fn, Ln, fibrin, Ln-5	Unknown
MT2-MMP (MMP-15)	Fn, tenascin, nidogen, aggrecan, perlecan, Ln	ProMMP-2, proMMP-13, CD44, MCP-3, tissue transglutaminase
MT3-MMP (MMP-16)	Collagen III, Fn, gelatin	ProMMP-2, tissue transglutaminase
MT5-MMP (MMP-24)	PG	ProMMP-2, tissue transglutaminase
<i>GPI-linked MMP</i>		
MT4-MMP (MMP-17)	Gelatin, fibrinogen	ProMMP-2
MT6-MMP (MMP-25)	Gelatin, collagen IV, fibrin, Fn, Ln	Unknown
<i>Type II transmembrane-type MMP</i>		
MMP-23	Gelatin	ProMMP-2
		Unknown

Major substrates of the MMPs are shown. Reproduced from Shiomi T., Lemaître V., D'Armiento J., Okada Y., 2010. Matrix metalloproteinases, a disintegrin and metalloproteinases, and a disintegrin and metalloproteinases with thrombospondin motifs in non-neoplastic diseases. *Pathology International* 60, 477–496.

Abbreviations: α 2-M, α 2-macroglobulin; α 1-PI, α 1-proteinase inhibitor; COMP, cartilage oligomeric matrix protein; CTGF, connective tissue growth factor; Fas-L, Fas ligand; FGF, fibroblast growth factor; Fn, fibronectin; HB-EGF, heparin-binding epidermal growth factor like growth factor; ICAM-1, intercellular adhesion molecule 1; IGFBP, insulin-like growth factor binding protein; Kit-L, kit ligand; Ln, laminin; MCP-3, monocyte chemoattractant protein-3; MMP, matrix metalloproteinases; MT-MMP, membrane-type MMP; PG, proteoglycan; proIL-1 β , pro interleukin-1 β ; Pro, proteinase type; ProMMP, latent MMP; proTNF- α , pro tumor necrosis factor- α ; proTGF- β , pro transforming growth factor β ; RANKL, receptor activator for nuclear factor κ B ligand; RASI-1, rheumatoid arthritis synovium inflamed-1; uPA, urokinase plasminogen activator.

interactions and signaling (Rodríguez *et al.*, 2010; Table 1). As individual MMP studies have become more focused, including proteomic studies and gene ablation models in mice, it has become clear that matrix proteins are not necessarily their only physiological or even pathological substrates. MMPs are responsible for the shedding of cell membrane proteins, including growth factors and cytokines and their receptors, cell adhesion molecules, and other proteins (Cauwe *et al.*, 2007; Lu *et al.*, 2011). MMPs also generate antimicrobial peptides, to activate or inactivate chemokines or cytokines, proteases and inhibitors, apolipoproteins, and complement components (Butler and Overall, 2009; Rodríguez *et al.*, 2010). With the discovery of the role of MMPs in the modulation of other proteases and their inhibitors in the extracellular environment, their consideration as one part of a complex interacting network of proteolytic activities, the 'protease web' has also emerged (Rodríguez *et al.*, 2010). Thus, many putative MMP substrates have been described by individual studies with different research interests. More recently rather more MMPs have been identified from the advent of the 'Degradomics' initiative. This uses proteomic techniques and the analysis of the cell and tissue proteomes in the presence versus the absence of a specific MMP. However the challenge of validation of these discoveries, in order to establish which are biologically important, still remains (Butler and Overall, 2009; Rodríguez *et al.*, 2010). Although less than ideal as a means to identify specific substrates of MMPs in humans, some interesting candidates have emerged from the analysis of transgenic mice (Gill *et al.*, 2010; Fanjul-Fernandez *et al.*, 2010). Validation, by comparing phenotypes of individual *Mmp* gene knockouts with the substrate gene ablation, has been valuable in this respect. Interpretation of the observations from *Mmp* gene ablation *in vivo* is complicated by protease web effects on other proteolytic activities and the possibility of downstream repercussions of the lack of activity in all tissues and the paucity of specific site ablations to date. It is interesting that the knockout of *Mmp* genes has few substantial developmental repercussions, with the exception of *Mmp-14* and, to a lesser extent, *Mmp-9*, *Mmp-13*, and *Mmp-20* (Page-McCaw *et al.*, 2007). This may be due the overlapping substrate profiles of many MMPs and the fact that proteases of other classes may also execute similar functions.

Currently identified MMP substrates and peptide cleavage site preferences are cataloged in the MEROPS, TOPFIND, and PMAP databases (recent aspects of this topic are reviewed in Butler and Overall, 2009; Rodríguez *et al.*, 2010; Lu *et al.*, 2011). Some potentially important substrates in both physiological and pathological processes are highlighted here. Although MMPs have been implicated in many human diseases there remain rather few definitive examples of primary causative roles.

ECM

The growth and remodeling of tissues in development or disease clearly demands the turnover of the ECM, notably the fibrillar collagens that are at the core of stromal tissues, and fibrin deposited during wound healing-related events. Although there are four MMPs defined as major fibrillar (type I,

II,III) collagen degrading activities (MMP-1, MMP-8, MMP-13, and MMP-14; note MMP-2, MMP-15, and MMP-16 also have weak activity), MMP-14 appears to be the major proteinase driving invasion through collagen when cells such as endothelial cells, fibroblasts, and macrophages invade the surrounding ECM (Willis *et al.*, 2013; Koziol *et al.*, 2012). It may also drive movement through fibrin matrices, a process key to wound healing. *In vitro* it is vital for cell growth in a 3D matrix environment (Rowe and Weiss, 2009). Of the other collagenases, there is definitive evidence that MMP-13, also known as collagenase-3, has *in vivo* collagenase activity in the mouse. *Mmp-13* null mice show an expansion of the zone of hypertrophic chondrocytes and a delay in apoptosis, indicating that MMP-13 is required for the transition from cartilage to bone at the growth plates of long bones. MMP-13 cleavage products of type II collagen and aggrecan can be recognized in a tight zone that is just distal to the zone of ossification and angiogenesis. The primary defect in *Mmp-13* deletion mutants is a failure of chondrocytes to remodel the ECM that is rich in type II collagen, as well as aggrecan. Further, *MMP-13* deletion mutants showed slower progression of an injury-induced arthritis model (Wang *et al.*, 2013). Loss of collagen II in human osteoarthritis is thought to be due to MMP-13 activity and recently developed specific inhibitors do prevent collagen loss. Evidence that the other 'collagenases,' MMP-1, MMP-8, and MMP-2; play major roles in direct collagen turnover *in vivo* remains sparse, although they have other important proteolytic roles (Page-McCaw *et al.*, 2007). Inactivating mutations in the *MMP-2* gene in humans leads to generalized osteolysis and severe osteoporosis, with arthritis in which marked progressive bone loss and joint destruction occurs. *Mmp-2*^{-/-} mice partially recapitulate the human disease due to developmentally restricted changes in osteoclasts and osteoblasts that may be due to changes in the supporting bone marrow cell system. This suggests a complex role for MMP-2 where its absence causes bone loss due to changes in the cells involved in both production and turnover. Murine MMP-1 (two forms, 'a' and 'b,' 'a' probably being the human MMP-1 homolog) is not expressed widely in the mouse and gene ablation studies suggest that protease-activated receptor1; PAR1 is a major target (Foley *et al.*, 2013). In wounded human skin, keratinocytes migrate off the basal lamina and encounter a dermal matrix rich in type I collagen; MMP-1 is thought to facilitate keratinocyte migration over the dermal matrix by lessening the affinity of collagen-integrin contacts (Pilcher *et al.*, 1997).

Many ECM proteins could be susceptible to breakdown by proteases of numerous classes and the identification of specific MMP actions in both physiological and pathological events can be gained from *in vivo* studies, for example, uncleaved galectin-3 is enriched specifically at the growth plate in *Mmp-9* null mice (Page-McCaw *et al.*, 2007). The NC1 domain of collagen XVIII is cleaved off by MMP-3,-9,-12,-13, -14 to generate the anti-angiogenic factor endostatin and plasminogen cleavage by MMP-2,-7,-9,-12 generates angiostatin that is also anti-angiogenic (Rodríguez *et al.*, 2010). MMP-2 and MMP-14 cleave the $\gamma 2$ chain of laminin-5 to release domain III, exposing a cryptic epitope that induces epithelial cell migration. Laminin-5 $\gamma 2$ fragment levels are reduced in *Mmp-14* null mice, suggesting a further mechanism by which this MMP may regulate cell movement.

Cytokines and Chemokines and Their Receptors

MMPs can proteolytically modify various cytokines and chemokines, as well as their release from ECM-binding sites, are now well established. Studies show the involvement of the MMPs in the generation of chemotactic gradients *in vivo*, for example, MMP-12 inactivates most members of the CXCL chemokine family (Rodríguez *et al.*, 2010; Hu *et al.*, 2007). MMPs are hence significant modulators of the initiation of both acute (endotoxic shock, myocardial infarction, and stroke) and chronic inflammatory conditions (autoimmune diseases and atherosclerosis), as well as ongoing disease activity and resolution. MMPs could have roles in angiogenesis by the release and activation of vascular endothelial growth factor vascular endothelial growth factor (VEGF) (MMP-1,-3,-7,-9,-14,-15,-19); MMP-9 activity has been confirmed in an *in vivo* model. bFGF is released from perlecan by MMP-1 or MMP-3 in endothelial cells and transforming growth factor β , TGF β is released from binding proteins such as the latent TGF β binding protein, LTBP complex, latency peptide, LAP, or decorin by MMP-2, -9, -13 or -14. However, MMP-released beta-glycan can bind to and act as a TGF β inhibitor (Rodríguez *et al.*, 2010; Cauwe *et al.*, 2007). Different MMP activities can promote or impair tumorigenic processes such as proliferation and apoptosis, contingent on the modulation of proteolysis of specific chemokines, growth factors, and receptors (Overall and Kleinfeld, 2006; Decock *et al.*, 2011; Hadler–Olsen *et al.*, 2013). MMP-9 expression is inversely associated with colorectal cancer metastasis which may be due to its ability to generate anti-angiogenic factors such as tumstatin and endostatin, but this is not proven. In a number of *in vivo* model studies with down-regulation or gene knockout of MMP-9, increased tumor development, progression, and metastasis was observed. On the other hand, the role of MMP-9 may be pro-tumorigenic in some stages of human cancers and the topic requires more detailed mechanistic study (Decock *et al.*, 2011; Vandooren *et al.*, 2013). Similar contradictory data exist for MMP-12 that has anti-tumorigenic activities in *in vitro* and *in vivo* models. The regulation of cytokine activities as well as protease inhibitors indicates that some MMPs have beneficial actions in immune-mediated events (Dufour and Overall, 2013). MMP-8 cleaves and activates interleukin-8 which is essential for the recruitment of neutrophils but its *in vivo* substrates are largely undefined as yet. In human cancer studies expression of MMP-8 was associated with prolonged survival in tongue squamous cell carcinoma. In breast cancer, plasma MMP-8 levels were positively associated with lymph node involvement but showed a negative correlation with the risk of distant metastasis (Decock *et al.*, 2011).

Cell–ECM and Cell–Cell Adhesion Molecules

Proteolytic modification of cell membrane proteins involved in cell adhesion could potentially be significant in the modulation of pathways associated with cell migration. These are of special relevance in tumorigenesis and angiogenesis. MMP-3 and MMP-7 disrupt E-cadherin interactions of epithelia. E-cadherin cleavage by MMPs has been linked to epithelial-to-mesenchymal transition associated with aggressive tumorigenesis. CD44 processing by MMPs facilitates cell

motility and transglutaminase that controls some ECM–integrin interactions is cleaved by MMP-2,-14,-15, and -16 (Cauwe *et al.*, 2007; Butler and Overall, 2009). MMP-14 has been shown to cleave a number of integrins or integrin precursors *in vitro* that can variously lead to their up- or down-regulation. Modulation of cell adhesion is a critical event in immune responses of leukocytes in inflammation and cancer, as well as numerous other pathologies (Cauwe *et al.*, 2007; Khokha Murthy and Weiss, 2013). Degradation of intercellular junction proteins in endothelia and in epithelia by MMPs are features of changes in permeability, for example, at the blood–brain barrier in cerebral ischemia and ischemia-related acute renal failure, respectively.

Intracellular Activities

Somewhat counter intuitive has been the recent description of MMP localization in nuclear, mitochondrial, vesicular, and cytoplasmic compartments including the cytoskeletal matrix and of ‘intracellular’ substrates for MMPs (Cauwe and Opdenakker, 2010; Butler and Overall, 2009). Proteomic approaches have demonstrated that a number of classical intracellular proteins are cleaved by MMPs, including apoptotic regulators, signal transducers, molecular chaperones, cytoskeletal proteins, systemic autoantigens, enzymes in carbohydrate metabolism and protein biosynthesis, transcriptional and translational regulators, as well as lysosomal and ubiquitination enzymes. Besides proteolysis inside cells, intracellular proteins may also be cleaved by MMPs extracellularly (Butler and Overall, 2009) since many intracellular proteins exit cells by nonclassical secretion mechanisms, or by various conditions of cell death by apoptosis, necrosis, etc. At this stage the relative importance of these activities *in vivo* is not clear.

Cellular Regulation of MMPs

Transcriptional

Pivotal modulators of cell signaling such as the MMPs necessarily have complex levels of regulation (Hadler-Olsen *et al.*, 2011). Few, or low levels, of MMPs are expressed by cells within resting tissues and they are induced in repair or remodeling processes and in disease or inflammation. At the gene level many hormones, cytokines and growth factors have been described as inducers of MMP-expression. Tissue specificity of expression of individual MMPs is mainly achieved by the combination of different transcriptional control mechanisms (Fanjul-Fernandez *et al.*, 2010). The integration of multiple signaling pathways, coupled with the cooperation between several *cis*-regulatory elements of the MMP promoters facilitates the strict spatiotemporal control of MMP- transcriptional activity. Additionally, epigenetic mechanisms, such as DNA methylation or histone acetylation, contribute to MMP regulation (Chernov and Strongin, 2012). Clinical studies have led to the identification of MMP polymorphisms and mutations causally implicated in the development of different genetic diseases (Fanjul-Fernandez *et al.*, 2010).

Posttranscriptional

This aspect of MMP biology is sparsely studied to date. mRNA stability and translational efficiency are apparent levels of regulation. Recent work has identified microRNAs that regulate MMPs, largely by translational repression or RNA target breakdown of upstream regulatory molecules (Fanjul-Fernandez *et al.*, 2010).

Posttranslational

At the posttranslational level there are also some interesting and novel regulatory mechanisms that are emerging. MMPs are synthesized in a latent 'pro' form in which a ~80 residue N-terminal propeptide harbors a cysteine residue that blocks the function of the catalytic zinc ion. Propeptide proteolysis is effected variously by autocatalytic mechanisms, probably initiated by allosteric changes in the MMP, by other MMPs, by the uPA/plasmin cascade, or by other cellular proteases. Mechanisms for the removal of the propeptide have been intensively analyzed *in vitro* (Hadler-Olsen *et al.*, 2011). Plasmin was originally identified as the major potential extracellular regulator of soluble MMPs, but it is still not clear which mechanisms are significant *in vivo*, for example, ablation of plasmin or plasminogen activators and of individual MMPs *in vivo* do not seem to prevent proMMP activation (Ra and Parks, 2007). The membrane associated MMPs and some others do appear to be activated by proprotein convertases such as furin within the secretory pathway. Potentially allosteric activation can also occur by interaction with other extracellular proteins or chemicals (Hadler-Olsen *et al.*, 2011). Such interactions may well turn out to be of some relevance *in vivo*, for example, MMP-7, MMP-2, and MMP-9 binding to proteoglycans facilitates auto-activation. MMP-9 is notable in that the extended linker sequence between the catalytic and hemopexin domains can be heterogeneously O-glycosylated. This O-glycosylated domain and its attached oligosaccharides (mucin-like) give substantial domain flexibility that modulate interactions with other proteins, for example, TIMP-1. MMP-14 also has an extensively N- and O-glycosylated linker with substantial heterogeneity that affects TIMP-2 binding and proMMP-2 activation, as well as its cellular turnover rate.

ProMMP-9 forms both homo and hetero-dimers involving the hemopexin-like domain and these can modulate its biochemical properties *in vitro* (Hadler-Olsen *et al.*, 2011; Vandooren *et al.*, 2013). In functional studies, Dufour *et al.* (2011) showed that MMP-9 multimers interact with CD44, leading to the activation of the EGF receptor and consequently the MAP kinase (extracellular signal-regulated kinases ERK1/2) pathway, thereby potentially mediating cancer cell migration. By targeting a compound to the hemopexin domain, that prevented the formation of multimers, cancer cell migration was abolished (Dufour *et al.*, 2011). Spatial regulation of MMPs may depend heavily on molecular interactions within the pericellular environment. The binding of specific secreted MMPs to cell surface receptors and other membrane proteins and ECM molecules can be invoked not only in the regulation of spatial activity, for example, CD151-MMP-7, CD44-MMP-9, and CD44-MT1-MMP; CD147 (EMMPRIN)-MMP-1, but also in regulation associated with endocytic mechanisms, for

example, Endo180-MMP-14-, low-density lipoprotein receptor-related protein-1, LRP-1-MMP-2, LRP-1-MMP-9, LRP-1-MMP-13 (Murphy and Nagase, 2011 and see below). MMPs are also down-regulated by classical endocytic mechanisms, such as clathrin coated pits or caveolae. MMP-14 may be protected from lysosomal destruction by association with tetraspanins.

Compartmentalization

The soluble MMPs are largely secreted proteins with conventional signal peptides and secretion through vesicular mechanisms and attendant regulatory processes. Polymorphonuclear leukocytes and mast cells store MMPs in vesicles and it is likely that some other cell types do similarly, although to a more limited extent. Some tumor and endothelial cells produce exosomes where vesicles persist in the extracellular space and can act as reservoirs of activity (Hadler-Olsen *et al.*, 2011). Such vesicles may be generated via diverse biological mechanisms triggered by pathways involved in oncogenic transformation, microenvironmental stimulation, cell activation, stress, or death. Exosomes are recognized as mediators of intercellular communication due to their capacity to merge with and transfer a repertoire of bioactive molecules to recipient cells. More recently MMPs have been localized in intracellular sites, for example, MMP-1,-2,-3,-9, and -13 have been found in the nucleus of different cell types but the trafficking mechanisms are not defined. Cytosolic localization has been described in various neuronal cells. Notably MMP-26 is thought to be largely located intracellularly (Hadler-Olsen *et al.*, 2011).

MMPs may be compartmentalized by association with both cell membrane and matrix proteins (Murphy and Nagase, 2011). Such interactions can orchestrate gradients or directionality of proteolytic activity and the modulation of signaling molecules. Interactions of MMPs with cell surface receptors are the basis of endocytic mechanisms to down-regulate MMP function outlined above. Although only a few MMPs have been studied, the diversity of mechanisms is enormous. These examples have led us to consider that many, if not all, of the MMPs may frequently function pericellularly, rather than at sites distal to the cells where the communication between the cells and the surrounding ECM and other bioactive molecules takes place.

Natural Inhibitors

The major natural inhibitors of the MMPs are α_2 -macroglobulin and the tissue inhibitors of metalloproteinases, TIMPs. α_2 -macroglobulin is a broad-spectrum protease inhibitor and probably largely has activities in the fluid phase of tissues. The TIMPs are the primary endogenous inhibitors; four forms (TIMPs-1-4) are found in the human and are 22–30 kDa proteins, consisting of an N-terminal metalloproteinase inhibitory domain (about 125 amino acids) and a C-terminal 'sub' domain (about 65 amino acids), each with three conserved disulfide bonds (Brew and Nagase, 2010; Murphy, 2011). The mechanism of TIMP inhibition is conserved across the MMPs, as shown by crystal structures of complexes between various

TIMPs and MMP-catalytic domains (Brew and Nagase, 2010). TIMP-3 is a key endogenous regulator of MMPs involved in ECM remodeling, inflammation, innate immunity, and cancer progression (Brew and Nagase, 2010).

Some TIMPs may interact with the hemopexin domain of specific MMPs and hence play additional biological roles, for example, the endocytic removal of MMP-2/TIMP-2 and MMP-9/TIMP-1 complexes. TIMP regulation of MMP function may itself be further regulated: receptor-mediated endocytosis occurs through low-density lipoprotein receptor-related protein 1, LRP-1 clearance of MMP-2 (complexed to thrombospondin-2 or TIMP-2) and MMP-9 (complexed to TIMP-1; Emonard *et al.*, 2005). TIMP-3 has more recently been shown to be endocytosed through LRP-1 (Scilabra *et al.*, 2013).

TIMPs regulate cell behavior independent of MMP inhibition, acting through specific cell-binding partners and signaling events. Cell signaling mechanisms mediated by TIMP-1 and TIMP-2 have been shown to promote cell proliferation, although the receptor-mediated events that are involved are not well understood. TIMP-1 has anti-apoptotic effects on some cell types, possibly acting by enhancing the activities of survival and differentiation factors in a signaling network that is mediated by the tetraspanin CD63 and by focal adhesion kinase, phosphoinositide 3-kinase and ERK. TIMP-2 binds to $\alpha 3 \beta 1$ integrin, leading to G1 phase growth arrest and enhanced *de novo* expression of the cyclin-dependent kinase inhibitor p27Kip1 (Bourboulia and Stetler-Stevenson, 2010). TIMP-3 has conflicting activities according to cell type. In some cells, it appears to promote the development of a transformed phenotype. On the other hand, TIMP-3 promotes apoptosis in several tumor cell lines and in smooth muscle cells, but this appears to involve the modulation of metalloproteinase activities. Work with *Timp-3*-null mice suggests that TIMP-3 can either promote or prevent apoptosis depending on the model system examined (Bourboulia and Stetler-Stevenson, 2010).

MMPs as Therapeutic Targets and Anti-Targets: The Use of Synthetic Inhibitors

MMPs observed functions at the ‘cutting edge’ of cell biology puts them into pivotal positions in the rapid response of cells to their environment by acting as key switches between different signaling pathways. Inevitably such enzymes should be regarded as suitable targets for therapeutic approaches to many diseases where such pathways become dysregulated. However, it is also now evident that some, as key regulators of immune responses, tissue repair, and other activities, may be classed as ‘anti-targets’ (Decock *et al.*, 2011; Dufour and Overall, 2013). A major challenge is therefore to identify which MMPs have driver roles in pathologies and could be therapeutic targets. The development of high-throughput proteomic techniques and conditional genetic modifications of mouse models is facilitating this process (Rodríguez *et al.*, 2010). A further hurdle for the development of specific inhibitors of catalysis has been the broad structural similarity of the metzincin catalytic site (Murphy, 2011; Tallant *et al.*, 2010). More detailed knowledge of active site structures has helped to some extent to resolve the problems associated with the development of more specific chemical inhibitors and selected

enzymes are now being targeted (Yiotakis and Dive, 2008). The role of exosites, both in the catalytic and hemopexin domains are being explored as determinants of substrate specificity of individual MMPs and, hence, as potential specific targeting sites for inhibitors (Hadler-Olsen *et al.*, 2011).

MMPs have well-defined roles in vascular diseases such as myocardial infarction, atherosclerosis, and aneurysms from associative studies of patient samples as well as transgenic mice and cell biological studies (Newby, 2012). Specific inhibitors of MMP-12 and MMP-13 have been developed that may be suitable for further assessment in cardiovascular diseases.

MMPs have also been implicated in blood–brain barrier dysfunction, demyelination, and the neuroinflammation and neurotoxicity underlying a range of neurological diseases, including multiple sclerosis, amyotrophic lateral sclerosis, and Alzheimer’s and Parkinson’s disease. Hence, MMP inhibition strategies have been proposed as for the treatment of multiple central nervous system (CNS) disorders. Data showing potential beneficial contributions of MMPs in key physiological and regenerative events in CNS disorders and injuries is emerging (Candelario-Jalil *et al.*, 2009; Hove *et al.*, 2012).

Imaging of MMPs

Functional analysis by genomic and proteomic techniques of MMPs *in vivo* has helped to elucidate MMP functions but studies are complicated by the many levels of posttranslational regulation and the modulation of other protease cascades. This is coupled with the challenge of designing specific active site probes, similar to the development of appropriate inhibitors. Hence *bona fide* tools for the study of this family *in vivo* have been slow to emerge. Activity-based probes have recently been designed using protein engineering to allow covalent probe–protease interactions that are useful in cell studies as proof of principle (Morell *et al.*, 2013). Fluorescence resonance energy transfer (FRET)-based probes with specific peptide sequences have been developed for MMP-12 and MMP-13 and used to image activity in an *in vivo* rodent inflammatory arthritis model (Lim *et al.*, 2013) and for MMP-13 in an osteoarthritis model (Ryu *et al.*, 2011).

MMP Activity in Drug Delivery Mechanisms

MMP activity has been used to activate cytotoxic agents *in situ*, for example, anthrax toxin in the tumor vasculature (Liu *et al.*, 2008), cytotoxic drugs coupled to nanocarriers (Samuelson *et al.*, 2013; Gao *et al.*, 2013). Vartak and Gemeinhart (2007) described the various strategies that have been adopted and have analyzed the factors that are key to successful prodrug development. As for the design of inhibitors and imaging agents, validation of the target MMP(s) and the design of cleavable peptide specificity are paramount.

Future Directions

The challenge to identify specific roles of the MMPs in development, tissue physiology, and pathology is still substantial

and no single level of investigation can suffice. The relevance of data from transgenic mice studies for the understanding of human disease remains under debate, hence efforts to study human tissue directly will be of exceptional value. At the cellular level there are many topics of outstanding interest particularly in relation to MMP trafficking and delivery at sites of activity and the relationship to cell-ECM dynamics (Lu *et al.*, 2011). The biomechanical properties of the ECM are key to cell behavior and some MMPs will have prominent roles in such processes by proteolytic modification of the tissue environment. For instance, study of ECM control of skeletal cell commitment and differentiation showed that MMP-14 in mesenchymal progenitor cells can regulate skeletal stem cell fate by changing their integrin interactions, Rho GTPase signaling and hence the nuclear transcription factors YAP and TAZ which control skeletal stem cell lineage commitment (Tang *et al.*, 2013).

The potential for MMPs as targets for therapeutic approaches is still regarded with skepticism by many and the need for further studies, particularly in human diseases has already been discussed. MMPs have not consistently been employed as biomarkers in disease as yet, although their potential as diagnostic and prognostic predictors of cancer is a burgeoning topic (Roy *et al.*, 2009). MMP-9 may be used as a marker of inflammatory pathologies and some cancers (Vandooren *et al.*, 2013), but this requires further critical analysis. Serum MMP-3 may be used to distinguish subjects with psoriatic arthritis from those with psoriasis alone and is an indicator of inflammation in rheumatoid arthritis patients. Further development of diagnostic tools capable of measuring MMP activities would advance the *in vivo* monitoring of therapeutic interventions in disease.

Glossary

Extracellular matrix (ECM) The highly organized and interconnected networks of proteinaceous and nonproteinaceous molecules (such as glycosaminoglycans and proteoglycans) that occupy the space around cells. ECM constitutes the scaffold that organizes each organ's hierarchical structure. It provides cells with an adhesive substrate that dictates cell polarity and regulates cell behavior. ECM endows organs with specific mechanical properties, best evident in connective tissues such as bone, tendon, and cartilage, and it has a crucial role in epithelia, where it comprises the basement membrane. The regulatory function of ECM is via direct cell-matrix interactions mediated by integrins, syndecans, and other receptors, as well as by sequestration of growth factors and cytokines, and release of bioactive ECM fragments termed matrikines.

Inherited connective tissue disorders A major category of human Mendelian disorders caused by gene mutations that affect the structure and function of connective tissue cells and their ECM. Examples include osteogenesis imperfecta (brittle bone disease), Ehlers–Danlos syndrome (causes weakness of blood vessels, skin, and internal organs), and Marfan syndrome, which affects the aorta, eyes, and skeleton.

Metzincins A class of secreted and cell-surface proteolytic enzymes characterized by a zinc-binding catalytic domain with a conserved three-dimensional structure. Protease families within the class primarily differ in regard to

additional (ancillary) domains located on the C-terminus of the catalytic domain. They constitute a major category of proteases that target ECM and cell-surface molecules, and are involved in cell migration, tissue destruction in disease, and cellular regulation by ectodomain shedding. Some metzincins (ADAM proteases, membrane-type matrix metalloproteinases (MT-MMPs), and meprins) are single-pass transmembrane molecules but the majority are secreted from cells (Astacin/tolloid/BMP-like proteases, most MMPs and all ADAMTS proteases).

Osteoarthritis (OA) A disorder of synovial joints characterized by progressive loss of articular cartilage leading to pain, swelling, and loss of joint function. In contrast to inflammatory arthritis, such as rheumatoid arthritis, which is primarily an autoimmune condition, OA is a degenerative condition resulting from altered joint mechanics, injury, or mild cartilage dysplasia, which leads to a cycle of progressive cartilage destruction and secondary inflammation.

Thrombotic thrombocytopenic purpura A hemostatic defect caused by unbridled platelet aggregation. Platelet aggregates occlude microvessels, and damage vital organs, with potentially fatal consequences. It is diagnosed by the presence of thrombocytopenia (reduced platelet count), anemia (reduced red blood cell count), and fragmented red blood cells damaged by their passage through the blocked microvessels.

Introduction, Defining Characteristics and Phylogeny of A Disintegrin-Like and Metalloprotease Domain with Thrombospondin Type 1 Motif Proteinases

At the time of its discovery, a disintegrin-like and metalloprotease domain with thrombospondin type 1 motif (ADAMTS1) was thought to be a variant disintegrin and metalloprotease domain (ADAM) because it has a similar catalytic domain active-site sequence (Kuno *et al.*, 1997). However, unlike ADAMs, ADAMTS proteases are not membrane anchored, and were found to have several distinguishing features (Hurskainen *et al.*, 1999). In particular, the ADAMTS ancillary (nonproteolytic) domains contain a canonical modular structure that always includes one or more thrombospondin type 1 repeats (TSRs, Figure 1). This characteristic domain organization, together with additional sequence and structural hallmarks (see below) clearly distinguishes the ADAMTS family from other zinc metalloproteases or metzincins, namely the matrix metalloproteinases (MMPs), astacin/BMP/tolloid/meprin proteases (astacins), and membrane-anchored ADAMs. All metzincins have structurally similar

catalytic domain folds and an active-site configuration with similar zinc-binding sequences and catalytic mechanisms. They are synthesized as proenzymes that subsequently undergo excision of the propeptide.

The zinc-binding sequence signature of the ADAMTS protease active site is of the repolysin or snake venom type (HEXXH + HD), indicating a closer evolutionary relationship to the membrane-anchored ADAMs rather than MMPs and astacins (Hurskainen *et al.*, 1999). Also, unlike many MMPs, but like all ADAMs, ADAMTS propeptide excision occurs through the proteolytic activity of proprotein convertases such as furin. However, the cysteine signature of the ADAMTS propeptide and catalytic domains is distinct from both MMPs and ADAMs; ADAMTS catalytic domain structures identified 4 disulfide bonds in ADAMTS1, 4 and 5, compared to 3 in ADAM17 and ADAM33, and none in the MMPs (Hurskainen *et al.*, 1999). Pioneering work of Kuno *et al.* on the prototypic ADAMTS protease, ADAMTS1, established its binding to the extracellular matrix (ECM, see glossary above), and the importance of the ancillary domain in this regard (Kuno and Matsushima, 1998; Kuno *et al.*, 1999). This point has assumed

Figure 1 Overview of mammalian ADAMTS proteases. The domain backbone shared by each ADAMTS protease is shown at the top, and the shared component modules are indicated in the box at left. The modular organization of the specialized evolutionarily related subclasses of ADAMTS proteases is indicated on the right. The additional C-terminal modules shown for each subgroup are added to the backbone at its C-terminus. The number of TSRs is indicated for each variant. Modules that are unique to each subgroup are explained at the bottom of the figure. Structural or functional characteristics that define each subgroup are shown at far right. Note that the Gon-1 related proteases are also proteoglycanases but are shown as a separate subclass. ADAMTS6 and 10 constitute a separate evolutionary subclass from ADAMTS17 and 19 but are shown together as they have the same modular organization. Reproduced from Apte, S.S., 2009. A disintegrin-like and metalloprotease (reprolysin-type) with thrombospondin type 1 motif (ADAMTS) superfamily: Functions and mechanisms. *Journal of Biological Chemistry* 284, 31493–31497. CUB, complement C1r/C1s, Uegf, Bmp1 domain; PLAC, protease and lacunin domain.

importance as a general ADAMTS characteristic, since ADAMTS catalytic domains alone generally lack proteolytic activity toward substrates.

Subsequent to discovery of ADAMTS1, the explosion of genome and transcript sequencing driven by the human genome project led to identification and molecular cloning of all family members. ADAMTS11 was misnumbered (it is identical to ADAMTS5); hence although there are 20 assigned ADAMTS numbers, there are only 19 ADAMTS proteases. Together with 7 ADAMTS-like proteins, they constitute the ADAMTS superfamily (Apte, 2009). ADAMTS-like proteins resemble the ancillary domains of ADAMTS proteases and some appear to be involved in similar processes and genetic disorders as the ADAMTS proteases. They are distinct gene products and not the result of alternative splicing of ADAMTS genes (Apte, 2009).

Phylogeny of the human ADAMTS family demonstrated the existence of numerous paralogs, subdividing the family into clades of paired or triplet paralogs, i.e., proteases with highly similar primary structure and domain organization (Figure 1; Apte, 2004; Huxley-Jones et al., 2005). ADAMTS proteases appear to be a metazoan innovation, since they are absent in bacteria, algae, and fungi. Completion of the genome of metazoans such as *Caenorhabditis elegans*, *Drosophila*

melanogaster, and *Ciona intestinalis* has facilitated understanding of the evolution of human ADAMTS genes. Humans and other vertebrates have significantly more ADAMTS genes than these organisms. Each of the human clades is rooted in one of 6 predicted *Ciona* ADAMTS proteases, indicating that the ancestral gene of each clade was present in an early chordate ancestor and subsequently underwent duplication (Huxley-Jones et al., 2005). ADAMTS13, the von Willebrand factor (vWF) protease, appears to be a vertebrate innovation, possibly related to development of a closed circulation and concomitant requirement for hemostasis, since an ortholog was not found in *Ciona* or protostomes. The so-called 'proteoglycanase' clade, highlighting a shared ability to cleave proteoglycans, is the largest and appears to be the most vertebrate-specific in regard to its amplification. Overall, phylogenetic analysis suggests that ADAMTS vertebrate gene expansion reflects sub-functionalization, i.e., expansion of structurally similar and functionally overlapping genes with emergence of some distinct characteristics, such as individual spatial-temporal expression patterns, rather than neo-functionalization (i.e., a stand-apart innovation such as ADAMTS13) (Huxley-Jones et al., 2005). Sub-functionalization is supported by work using gene knockout mice that demonstrated cooperativity of ADAMTS paralogs during morphogenesis.

Domain Organization and 3-Dimensional Structure

With the exception of ADAMTS13, whose propeptide is short (Majerus *et al.*, 2003), ADAMTS proteases have a propeptide of > 200 residues that typically contains 3 Cys residues. A consensus proprotein convertase (e.g., furin) processing site (RXK/RR↓) is present at the junction of the propeptide and catalytic domain. The exception is ADAMTS10, which has a suboptimal furin processing site (GLKR) at this junction (Kutz *et al.*, 2011). However, like most other ADAMTS proteases, it has 1–2 additional furin cleavage sites within the propeptide. The ADAMTS catalytic domain and disintegrin-like domain are believed to constitute a single functional unit, and all downstream modules are regarded as constituting the ADAMTS ancillary domain. The core ancillary domain comprises TSR1, the cysteine-rich domain (CRD) and the spacer, which lacks Cys residues. TSR1 is highly conserved among ADAMTS family members. The CRD and spacer are followed in every ADAMTS except ADAMTS4 by one or more additional TSRs. Many ADAMTS proteases have a small, cysteine-rich C-terminal PLAC (protease and lacunin) module or other characteristic C-terminal domains (Figure 1). In ADAMTS7 and ADAMTS12 the TSR array is interrupted by a mucin domain, which contains glycosaminoglycan (GAG) attachment sites (Somerville *et al.*, 2004). Few ADAMTS splice variants have been reported. One, in ADAMTS4, alters the sequence of its spacer module, with no apparent significant impact on proteolytic specificity (Wainwright *et al.*, 2013). ADAMTS20 has a short splice variant that excludes 4 C-terminal TSRs and the Gon-1 domain, and appears to be the dominant ADAMTS20 transcript, whereas splicing in the ADAMTS9 propeptide and TSR array are known (Dubail *et al.*, 2014; Rao *et al.*, 2003), but have not been functionally investigated.

Because of inherent challenges in expressing and purifying these large, complex proteases, a high-resolution three-dimensional structure is presently unavailable for a full-length ADAMTS protease. A low resolution structure of ADAMTSL1/punctin-1, comprising the core ancillary domain and 3 TSRs was obtained by rotary shadowing electron microscopy and showed a hockey-stick like structure with a globular structure with an attached extended segment (Hirohata *et al.*, 2002). 3-dimensional structures obtained by X-ray crystallography are currently known for the catalytic + disintegrin-like domain of ADAMTS1, ADAMTS4, and ADAMTS5, both in apo-form and inhibitor-bound (Gerhardt *et al.*, 2007; Mosyak *et al.*, 2008; Shieh *et al.*, 2008). These studies used different preparation methods – ADAMTS1 catalytic domain + disintegrin-like domain was expressed in insect cells, ADAMTS5 catalytic domain was refolded from *Escherichia coli* inclusion bodies, and the ADAMTS4 and ADAMTS5 catalytic domain + disintegrin-like domains were purified from transfected CHO cells. Nevertheless, all structures closely resembled each other and identified several unifying features of ADAMTS proteases. The overall catalytic domain fold was similar to previously determined structures of the MMP and ADAM family members in regard to α/β structure, but differed in regard to specific loops joining β -strands and α -helices. The ADAMTS catalytic domains differed from MMPs and ADAMs in having 4 disulfide bonds and two calcium-binding sites, as well as a deeper active-site pocket containing the catalytic zinc atom. ADAMTS13

reportedly has three calcium-binding sites. An extended 9-residue strand connected the catalytic domain to the smaller disintegrin-like domain, bringing it in close proximity to the active site, suggesting it could contribute an auxiliary substrate (or inhibitor)-binding surface of the protease (Gerhardt *et al.*, 2007; Mosyak *et al.*, 2008). That the catalytic and disintegrin-like domains act as a functional unit is also supported by the domain structure of ADAMTS-like proteins, which do not have either of these domains (Hirohata *et al.*, 2002). Comparison of the ADAMTS4 and ADAMTS5 catalytic domains with or without bound inhibitor, i.e., the Apo forms, identified a dynamic active-site configuration, i.e., an autoinhibited ‘non-binding’ closed form and an open ‘binding’ form (Mosyak *et al.*, 2008). In its open state, the inhibitor-bound active sites were similar to those of MMPs and ADAMs, albeit with differences in local pockets, and showed a Zn atom coordinated by three conserved histidines. The S2’ pocket was formed by a short disulfide-containing loop with the motif CGxxxxCDTL, which was proposed as a unique feature of ADAMTS proteases. In the unliganded state, this loop moves from an open position toward the catalytic zinc by ~ 8 Å, resulting in removal of bound calcium and repositioning of the disulfide bridge. It was postulated that the open and closed forms coexisted in equilibrium, with the mobility of the active-site responsive to the dynamic nature of their proteoglycan substrates (Mosyak *et al.*, 2008).

The fold of the disintegrin-like domains resembles the CRD of the ADAM proteases, and despite sequence identity with the disintegrins (hence the name disintegrin-like), has only partial structural homology to snake venom disintegrins (Gerhardt *et al.*, 2007; Mosyak *et al.*, 2008). Determination of the crystal structure of the non-catalytic domains of ADAMTS13 (disintegrin-like, TSR1, CRD, and spacer) was a landmark in visualizing ADAMTS proteases (Akiyama *et al.*, 2009). It showed that the N-terminal portion of the ADAMTS CRD (designated C_A) resembled the disintegrin-like domain and the ADAM CRDs (although it lacked sequence homology to them), whereas the C-terminal part of this domain, designated C_B, formed a short rod, bridging C_A to the spacer. The C_A and spacer domains made direct contact. The spacer domain, which has no sequence homologies outside the ADAMTS family, and lacks Cys residues, folded into a single globular domain with 10 β -strands in a jellyroll topology, forming two obliquely facing antiparallel β -sheets. Together with structure-based mutagenesis of ADAMTS13, Akiyama *et al.* (2009) identified three VWF-binding exosites on the linearly aligned discontinuous surfaces of the disintegrin-like, cysteine-rich, and spacer domains (Wu *et al.*, 2006).

The structure of TSR1 of ADAMTS13 was analogous to the previously determined structure of TSRs 2 and 3 of the ECM protein thrombospondin-1 (TSP1) (Tan *et al.*, 2002), and comprised an antiparallel 3-stranded fold with rigidity provided by stacked Arg and Trp residues (Akiyama *et al.*, 2009). The single TSR of ADAMTS4 was modeled based on the structure of the TSP1 TSRs, and positive charges were found to cover nearly an entire face, potentially explaining the high affinity of this TSR for sulfated GAG chains of aggrecan (Tan *et al.*, 2002). In addition to GAG-binding, which could mediate cell-surface and substrate binding, a postulated function of TSRs could be to mediate proper spacing of exosites. TSR2

and TSR3 of TSP1 were arranged as an extended rigid structure with tilt and twist angles of 30° and 180° between the TSRs (Tan *et al.*, 2002). However, the precise relationship between tandem TSRs of ADAMTS proteases will depend on the sequences of the linkers between them, and is yet to be determined.

Because of strict conservation of all cysteine residues in the ancillary domain, as well as of numerous hydrophobic residues in all domains that provide additional stabilization, it is very likely that all ADAMTS proteases will have a similar structural backbone. Differences in surface residues and of peripheral loop length and sequence likely mediate different substrate binding by the various ADAMTS proteases. Three-dimensional structures for an ADAMTS propeptide and of C-terminal domains such as the Gon-1 domain and PLAC domain are presently unavailable.

Biosynthesis and Regulation

ADAMTS proteases are directed to the secretory pathway by a signal peptide, which is removed co-translationally. ADAMTS proteases (except ADAMTS4) have N-linked oligosaccharide attachment sites that are also modified co-translationally. The propeptide as well as its N-glycans were found to be crucial for secretion of the ADAMTS9 catalytic domain (Koo *et al.*, 2007), but appear not to be essential for secretion of ADAMTS13 (Majerus *et al.*, 2003). Similarly, propeptide N-glycosylation of a worm ADAMTS named MIG-17 was crucial for its localization during gonad morphogenesis (Nishiwaki *et al.*, 2004). The ADAMTS13 propeptide is unusually short (41 residues) and dispensable for maintenance of quiescence or folding of downstream domains (Majerus *et al.*, 2003). Many ADAMTS TSRs undergo two unusual and specific posttranslational modifications, named C-mannosylation and O-fucosylation. C-mannosylation occurs on W^o residues in W^oXXW⁺ motifs and has been documented in an ADAMTS-like protein, ADAMTSL1 (punctin-1), but its functional significance is presently unknown (Wang *et al.*, 2009). Because the modification occurs on unfolded peptides, it is thought to occur co-translationally. The C-mannosylation consensus sequence is most frequently present in TSR1, consistent with its high degree of conservation (Wang *et al.*, 2009).

O-fucosylation is the addition of fucose or glucose β 1-3fucose disaccharide to Ser/Thr residues within the consensus sequence CXX(S/T)CG by the tandem activity of protein O-fucosyltransferase 2 (POFUT2) and β 1,3-glucosyltransferase (B3GLCT, previously known as B3GALTL) (Luo *et al.*, 2006). This modification was shown to be a crucial requirement for efficient secretion of ADAMTS13 and ADAMTSL1 (Ricketts *et al.*, 2007; Wang *et al.*, 2007), and could constitute a form of protein quality control within the ER, since it does not occur on unfolded peptides. A human genetic disorder resulting from B3GLCT mutations, named Peters Plus syndrome (Lesnik Oberstein *et al.*, 2006), affecting the eyes and other organs, may result at least in part from reduced secretion of several family members, since half of its predicted substrates are ADAMTS proteins. ADAMTS7 and ADAMTS12 contain predicted sites for attachment of GAG chains within their mucin domains. ADAMTS7 was shown to be modified by attachment

of chondroitin sulfate, thus rendering it a proteoglycan, an unusual modification that was previously undocumented in a protease (Somerville *et al.*, 2004).

Once secreted, many ADAMTS proteases are susceptible to *trans*- or autocatalytic proteolysis within the ancillary domain. This is a poorly studied phenomenon that potentially can be activating, generate new or promiscuous activities, or inactivate the protease through loss of substrate-binding exosites. Cell-surface heparan sulfate proteoglycans such as syndecans have been proposed as an activation mechanism for aggrecanases that leads to MMP cleavage of the ancillary domain (Gao *et al.*, 2003; Echtermeyer *et al.*, 2009).

Protease inhibitors active against ADAMTS proteases include TIMP-3, one of a family of four tissue inhibitors of metalloproteases, which are well-known MMP inhibitors, and α 2-macroglobulin (Gendron *et al.*, 2003; Hashimoto *et al.*, 2001; Tortorella *et al.*, 2004). Inhibition of ADAMTS proteases by TIMP-3 reflects the close relationship of the ADAMTS catalytic domain fold to that of MMPs and ADAMs. A chondroprotective role for TIMP-3 is suggested by increased cartilage breakdown in *Timp3*^{-/-} mice (Mahmoodi *et al.*, 2005). Polyanions such as calcium pentosan polyphosphate are thought to reduce cartilage breakdown in part by enhancing TIMP-3 affinity for aggrecanases (Troeborg *et al.*, 2008). ADAMTS4 and ADAMTS5 are endocytosed by the scavenger receptor low-density lipoprotein receptor-related protein 1 (LRP1) (Yamamoto *et al.*, 2013). LRP1 binds them with different affinities raising the possibility that ADAMTS5, which binds more strongly, may be a competitor for LRP1 endocytosis of ADAMTS4. ADAMTS interacts with LRP1 via its cysteine-rich and spacer domains, whereas ADAMTS4 binds via TSR1 and the spacer (Yamamoto *et al.*, 2013).

Mechanistic Basis of Genetic and Acquired Disorders Involving ADAMTS Proteases

An important viewpoint for understanding the outcomes of ADAMTS mutations, indeed applicable to any protease, is that the biology of a protease is really the biology of its substrates. Mendelian disorders resulting from ADAMTS mutations (Table 1), albeit rare, provide insights on ADAMTS function in relation to the biology of specific substrates and the processes and pathways they participate in. Although numerous disease associations of ADAMTS proteases have been reported from transcriptome analysis and genome-wide association analysis, especially in cancer, the author have focused here on disease and functional roles that are well substantiated by altered cleavage of a specific substrate. An extensive literature has accumulated on three such ADAMTS-substrate relationships that illuminate disease mechanisms:

ADAMTS13, vWF and Thrombotic Thrombocytopenic Purpura

ADAMTS13, also known as the vWF-protease, appears to have no substrates other than vWF. vWF is synthesized by endothelial cells and megakaryocytes, and is released as ultra-large string-like structures which provide a markedly adhesive substrate for platelets (Zheng *et al.*, 2002). vWF binds glycoprotein

Table 1 Mendelian disorders resulting from ADAMTS mutations

Mendelian disorder	MIM number	Gene/chromosomal locus	Inheritance
Ehlers–Danlos syndrome (EDS), dermatosparaxis type or (VIIC)	225410	ADAMTS2, 5q35.3 (Colige <i>et al.</i> , 1999)	Autosomal recessive
Weill–Marchesani syndrome 1/Weill–Marchesani syndrome, autosomal recessive/mesodermal dysmorphodystrophy, congenital	277600	ADAMTS10/19p13.2 (Dagoneau <i>et al.</i> , 2004)	Autosomal recessive
Thrombotic thrombocytopenic purpura, congenital/Upshaw–Schulman syndrome	274150	ADAMTS13, 9q34.2 (Levy <i>et al.</i> , 2001)	Autosomal recessive
Weill–Marchesani-like syndrome	613195	ADAMTS17, 15q26.3 (Morales <i>et al.</i> , 2009)	Autosomal recessive
Microcornea, myopic chorioretinal atrophy, and telecanthus (MMCAT)	615458	ADAMTS18, 16q23.1 (Aldahmesh <i>et al.</i> , 2013)	Autosomal recessive

1b on the platelet surface and to collagen in sub-endothelium of damaged vessels. ADAMTS13, which is primarily secreted by stellate cells in the liver, and to a lesser extent by vascular endothelial cells, megakaryocytes, and platelets, cleaves the vWF strings at the Tyr¹⁶⁰⁵-Met¹⁶⁰⁶ peptide bond in the A2 domain to reduce their prothrombogenic propensity (Zheng *et al.*, 2002). ADAMTS13 is particularly efficient when vWF strings are stretched by circulatory shear force. Shear force extends the A2 domain, exposing the scissile bond, which can also be induced by denaturants such as urea, which is used in biochemical assays for plasma ADAMTS13 activity. Loss of ADAMTS13 activity to less than 5% of normal, resulting most commonly from autoantibodies (acquired thrombotic thrombocytopenic purpura (TTP)) or rarely, from ADAMTS13 mutations (congenital TTP), leads to unbridled platelet thrombogenesis (Zheng, 2013). Most autoantibodies formed in TTP react with the CRD and spacer module, most commonly the latter, and correspond to ADAMTS13 surface regions comprising exosites for vWF processing (Zheng, 2013). Additionally, the ADAMTS13 TSRs contain free thiols that may prevent higher order complex formation of vWF and reduce vWF mediated platelet aggregation. Coagulation factor VIII binds vWF with high affinity and can facilitate vWF cleavage under shear stress conditions, possibly by increasing unfolding of the vWF-A2 domain. Platelet glycoprotein 1b α , which binds vWF, also enhances cleavage of multimeric vWF by ADAMTS13. *Adamt13* deficient mice develop TTP, but only when challenged with shigatoxin or recombinant vWF (Motto *et al.*, 2005). Shigatoxin binds to A1-A2 domains of vWF and interferes with processing by ADAMTS13 (Nolasco *et al.*, 2005). Thus, the highly specific ADAMTS13-vWF interaction is clearly influenced by environmental and genetic factors. Reduced plasma ADAMTS13 activity is a risk factor for myocardial infarction, cerebral stroke, preeclampsia, and cerebral malaria (Zheng, 2013).

ADAMTS2, Procollagen Processing and Dermatosparaxis

Fibrillar collagens (e.g., collagen types I, II, III, V, XI) are synthesized as procollagens with bulky N- and C-terminal propeptides that preclude assembly into tightly packed fibrils. Hence they are excised prior to assembly, with ADAMTS proteases thought to remove the N-propeptides of procollagens I,

II, and III. ADAMTS2 mutations cause Ehlers–Danlos syndrome (dermatosparactic type) (Colige *et al.*, 1999), a connective tissue disorder first identified in cattle and named dermatosparaxis (Lapiere and Nusgens, 1993) and subsequently in humans (Colige *et al.*, 1999). In this disorder, there is failure to excise the amino-propeptide of procollagen I in the dermis of skin. The retained propeptide hinders collagen fibril assembly, and the resulting thin, ribbon-like, and branched fibrils are mechanically weak, resulting in severe skin fragility (Lapiere and Nusgens, 1993). However, arteries, bone, and tendon, which also contain collagen I as a major constituent, are not as fragile, very likely because of compensating procollagen processing activity possibly provided by ADAMTS3 (Fernandes *et al.*, 2001) and/or ADAMTS14 (Colige *et al.*, 2002). Recently, ADAMTS3, was shown to process the pro-lymphangiogenic factor VEGF-C, converting the 29/31-kDa pro-form of VEGF-C to the mature 21/23-kDa form, which is active in signaling (Jeltsch *et al.*, 2014).

ADAMTS10, Tissue Microfibrils and Weill–Marchesani Syndrome

Tissue microfibrils are macromolecular complexes in ECM comprising fibrillins and other proteins. During the embryonic period, fibrillin-2 predominates, and most adult microfibrils comprise fibrillin-1. In particular, the ocular zonule, which suspends the ocular lens in the optic path, is a cell-free structure almost entirely composed of fibrillin-1 microfibrils. In addition to providing structural support, microfibrils regulate storage and activation of transforming growth factor- β (TGF β) and related growth factors. Recessive ADAMTS10 mutations cause Weill–Marchesani syndrome (WMS1), in which the lens is dislocated (ectopia lentis), leading to severe eye problems; affected individuals are short, with short hands and feet and have thick skin, stiff joints, and heart defects (Dagoneau *et al.*, 2004). ADAMTS17 mutations cause a similar syndrome (Table 1), except that brachydactyly, joint stiffness, and heart defects are absent (Morales *et al.*, 2009). Intriguingly, fibrillin-1 mutations lead to ectopia lentis as an isolated disorder, as well as to dominantly inherited WMS, which was suggestive of a functional link between ADAMTS10 and fibrillin-1 (Faivre *et al.*, 2003). Indeed, ADAMTS10 binds to fibrillin-1 and is found in microfibrils in skin and the zonule (Kutz *et al.*, 2011).

ADAMTS10 cleaves fibrillin-1, although it does so inefficiently, and was found to enhance microfibril assembly in cultured fibroblast. The relationship of ADAM17 to fibrillins is presently unknown. Two other superfamily members, ADAMTSL2 and ADAMTSL4 also have a strong genetic relationship to fibrillin-1, which was reviewed recently (Hubmacher and Apte, 2011).

ADAMTS Proteases as Aggrecanases in Osteoarthritis

The hallmark of articular cartilage ECM is an abundance of the highly sulfated proteoglycan aggrecan, which forms large complexes with hyaluronan (HA) that are constrained by a collagenous network, primarily comprised of collagen II (Heinegard and Saxne, 2011). This combination and arrangement of ECM components is responsible for the weight-bearing properties of cartilage. Proteolysis of aggrecan and its subsequent release from cartilage was identified as a major pathogenic mechanism in osteoarthritis (OA) (Lark *et al.*, 1997). ADAMTS4 and subsequently, ADAMTS5, were isolated as the activities responsible for aggrecan loss (Abbaszade *et al.*, 1999; Tortorella *et al.*, 1999). Both proteases cleave aggrecan at multiple sites, but cleavage at the Glu³⁷³-Ala³⁷⁴ site is the most deleterious, since it releases the bulk of aggrecan from its anchorage to HA. Analysis of mice with mutant ADAMTS4 and ADAMTS5 determined that ADAMTS5 was the major aggrecanase, because *Adamts5* mutant mice were resistant to both surgically induced and inflammatory arthritis (Glasson *et al.*, 2005; Stanton *et al.*, 2005). Furthermore, mutagenesis of the Glu³⁷³-Ala³⁷⁴ scissile bond in mice prevented cartilage destruction (Little *et al.*, 2007). With this stringent demonstration of causality, ADAMTS4 and ADAMTS5 are considered as major drug targets in arthritis. Although ADAMTS1, ADAMTS9, and other ADAMTS proteases cleave aggrecan, they do so inefficiently and are not as rigorously associated with cartilage destruction in OA as ADAMTS4 and ADAMTS5 (Fosang and Little, 2008; Little *et al.*, 2005).

Functions in Mammalian Development Gleaned from Mouse Mutants

Several phenotypes are now known from mouse mutants, which are summarized in Table 2 and whose underlying mechanisms are understood to varying degrees. *Adamts1* deficient mice have reduced survival immediately after birth, for reasons that are poorly understood, and mice that do survive have stunted growth (Shindo *et al.*, 2000). *Adamts1* deficient mice have structural defects of the urinary tract, such as hydronephrosis, which can result from distal occlusion of urinary flow (Shindo *et al.*, 2000; Mittaz *et al.*, 2004). *Adamts2*-deficient mice have dermatosparaxis, as well as male infertility, the basis of which is not presently understood (Li *et al.*, 2001). *Adamts5* deficient mice are externally normal, but have pulmonic valve stenosis, bicuspid aortic valves, and myxomatous mitral valves (Dupuis *et al.*, 2011, 2013). *Adamts9*-deficient mice do not survive past gastrulation in the early embryo (Dubail *et al.*, 2014; Enomoto *et al.*, 2010), whereas mice homozygous for a spontaneous *Adamts20* mutation (*belted/bt*) survive and are apparently normal but for a belt of unpigmented skin around their torso (Rao *et al.*, 2003; Silver *et al.*, 2008). Among the ADAMTS mutant mice reported to date, only *Adamts4* and *Adamts12* mutants are developmentally normal, fertile, and have a normal lifespan (Stanton *et al.*, 2005; Boerboom *et al.*, 2011; El Hour *et al.*, 2010). However, data from combinatorial crosses of a number of ADAMTS genes suggests that the functions of ADAMTS4 and ADAMTS12 in these mice could be masked by compensation by their paralogs. Indeed, mice lacking both *Adamts1* and *Adamts4* die at birth and have severe thinning of their renal medulla (Boerboom *et al.*, 2011).

ADAMTS Proteolysis of Versican as a Crucial Requirement for Normal Embryogenesis and Neural Function

During organogenesis, the embryo ECM is of a provisional/temporary nature, rich in proteoglycans such as versican,

Table 2 Phenotypes arising from inactivation of mouse ADAMTS genes

Gene	Phenotype
<i>Adamts1</i> ^a	Lethal at birth, urogenital anomalies, myocardial non-compaction, and female infertility (Shindo <i>et al.</i> , 2000; Mittaz <i>et al.</i> , 2004; Stankunas <i>et al.</i> , 2008; Brown <i>et al.</i> , 2010)
<i>Adamts2</i>	Skin fragility and male infertility (Li <i>et al.</i> , 2001)
<i>Adamts4</i> ^a	No discernible phenotype reported (Stanton <i>et al.</i> , 2005)
<i>Adamts5</i> ^a	Pulmonic valve stenosis, mitral valve myxoma, and soft tissue syndactyly affecting hindlimbs (Dupuis <i>et al.</i> , 2011, 2013; McCulloch <i>et al.</i> , 2009)
<i>Adamts9</i> ^a	Lethal very early during embryogenesis (<i>Adamts9</i> −/−); variable cardiovascular anomalies (<i>Adamts9</i> +/−); ocular anterior segment dysgenesis (<i>Adamts9</i> +/−); soft tissue syndactyly (limb-specific conditional deletion) (Dubail <i>et al.</i> , 2014; Enomoto <i>et al.</i> , 2010; McCulloch <i>et al.</i> , 2009; Kern <i>et al.</i> , 2010; Koo <i>et al.</i> , 2010)
<i>Adamts12</i>	No developmental phenotype reported (El Hour <i>et al.</i> , 2010)
<i>Adamts13</i>	Thrombotic thrombocytopenia (Motto <i>et al.</i> , 2005)
<i>Adamts20</i> ^a	White belly spotting, soft tissue syndactyly affecting forelimbs (Rao <i>et al.</i> , 2003; Silver <i>et al.</i> , 2008; McCulloch <i>et al.</i> , 2009)

^aAdditional phenotypes were reported after combinatorial deletion with other ADAMTS alleles. *Adamts1* −/−; *Adamts4* −/− mice died within 72 h of birth and had dilated renal pelvis and thinned medulla (Boerboom *et al.*, 2011); *Adamts5* −/−; *Adamts20* −/− and *Adamts5* −/−; *Adamts9* +/− mice have greater penetrance of soft tissue syndactyly than either allele deletion alone (McCulloch *et al.*, 2009); *Adamts20* −/−; *Adamts9* +/− newborn mice have cleft palate and more severe white spotting than *Adamts20* −/− alone and die at birth (Enomoto *et al.*, 2010; Silver *et al.*, 2008).

fibronectin, and HA. As the embryo matures, and continuing into the juvenile period, provisional ECM transitions to a mature ECM containing abundant collagen, elastin, and other specialized components. Analysis of ADAMTS mutant mice has suggested that several ADAMTS proteases, such as ADAMTS1, ADAMTS4, ADAMTS5, ADAMTS9, ADAMTS15, and ADAMTS20, collectively termed proteoglycanases, participate in versican remodeling, and may work cooperatively to dismantle the provisional ECM (reviewed recently in [Nandadasa et al., 2014](#)). During the process of myocardial compaction, the versican-HA rich cardiac jelly is remodeled by ADAMTS1 ([Stankunas et al., 2008](#)). Failure of sculpting of developing pulmonic valve leaflets in *Adamts5* $-/-$ mice is a consequence of reduced cleavage of versican, since the valve phenotype can be ameliorated by reduction of versican ([Dupuis et al., 2011](#)). Reduced melanoblast colonization of skin in *Adamts20*^{bt/bt} mice is associated with reduced processing of versican in the dermis of skin ([Silver et al., 2008](#)). Mice doubly deficient in *Adamts5*, *Adamts9*, or *Adamts20* develop soft tissue syndactyly owing to failed apoptosis in interdigital web mesenchyme, accompanied by loss of versican proteolysis ([McCulloch et al., 2009](#)). Although mice singly deficient in *Adamts5* and *Adamts20* have a low penetrance of syndactyly, it is fully penetrant in mice with limb-specific deletion of *Adamts9*. The N-terminal product of versican proteolysis by ADAMTS proteases, named versikine, has been shown to induce cell death in ADAMTS-deficient interdigital webs, in which apoptosis was reduced ([McCulloch et al., 2009](#)). *Adamts9* and *Adamts20* combined deficiency leads to death at birth from a complete cleft of the secondary palate where reduced versican proteolysis is observed ([Enomoto et al., 2010](#)). These mice also have more extensively depigmented skin than *Adamts20*^{bt/bt} mice ([Silver et al., 2008](#)).

The central nervous system ECM is rich in proteoglycans, including the ADAMTS substrates aggrecan, brevican, and versican. These HA-binding molecules are particularly enriched in perineuronal nets and in glial scars. Based on upregulation of ADAMTS1, ADAMTS4, ADAMTS5, and ADAMTS9 in neural injury, it has been proposed that they have a role in mediating inflammation, repair, vascular perfusion, and neuronal plasticity. ADAMTS proteases are primarily expressed by astrocytes and expressed in several neuronal structures. ADAMTS4 cleaves brevican at the E395-S396 site and the resulting cleaved brevican can enhance glioma cell migration ([Matthews et al., 2000](#); [Viapiano et al., 2008](#)). ADAMTS4 and ADAMTS5 can cleave reelin, an ECM molecule involved in neural development and plasticity ([Hisanaga et al., 2012](#); [Koie et al., 2014](#); [Krstic et al., 2012](#)).

ADAMTS1 and Female Infertility

Adamts1 is expressed in a hormone-dependent manner during the ovulatory cycle and upregulated by the preovulatory surge of luteinizing hormone in female mice. ([Robker et al., 2000](#); [Russell et al., 2003](#)). Female *Adamts1* $-/-$ mice are subfertile due to impaired ovulation, with mature oocytes remaining trapped in unruptured follicles ([Brown et al., 2006, 2010](#)). ADAMTS1 is required for the proper assembly of the cumulus oophorus complex (COC) ECM, and is responsible for proteolysis of versican in the COC that is required for follicular

rupture and release of the oocyte. ADAMTS1 is also required for clearance of residual versican remaining after fertilization. Versican proteolysis by ADAMTS1 may be crucial for sperm penetration through the cumulus barrier prior to fertilization. ADAMTS1 and versican cleavage were associated with fertilization capacity in human oocytes. ADAMTS1 was also shown to have a role in ensuring ovarian angiogenesis and lymphangiogenesis ([Brown et al., 2006](#)) through mechanisms that are not understood.

Current Directions and Challenges

Because of the relatively recent discovery of ADAMTS proteases, their full range of biological roles remains to be unearthed. Nevertheless, it is already clear that they are extremely significant in mammalian development and human disorders. Indeed, more human genetic disorders are associated with this family than other metzincins. Their detrimental role in arthritis stimulated a great deal of interest in generating agents to block their activity, but current interest in these has waned because the normal functions of aggrecanases are not yet well understood, and there is a fear of side-effects or off-target effects. There is considerable interest in recombinant ADAMTS13 for treatment of, and engineering it to avoid targeting by autoantibodies. There have been numerous reports of altered expression of ADAMTS genes in cancer as well as their identification as tumor suppressors in various cancers, but no pivotal, direct, causal association with cancer has yet become apparent. ADAMTS1 and ADAMTS9 have been shown to be anti-angiogenic, which may be relevant to potential roles in cancer. Protein chemistry and substrate identification for this family is challenging because of the difficulty in obtaining full-length ADAMTS proteases, and the role of cofactors such as fibulins, remains to be fully explored. Relatively little is known about ADAMTS proteins in the brain and this is likely to be a fertile area for future research. Finally, very little is known about the transcriptional regulation of ADAMTS genes. This is a field with considerable potential for new discoveries.

ADAMs Regulate Cell–Cell Interactions by Controlling the Function of the EGF-Receptor, TNF α and Notch

CP Blobel, Hospital for Special Surgery, New York, NY, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

ADAM A disintegrin and metalloproteinase; conditional knockout mice, mice engineered to carry loxP recombination sites surrounding a gene of interest, this gene can be conditionally inactivated in a specific cell type or tissue or in a temporal manner if the Cre-recombinase,

which deletes the sequence between the loxP sites, is expressed under the control of a tissue specific promoter, or a promoter that can be induced in a temporal manner.

Notch A membrane-anchored transcription factor that is activated by proteolytic processing, mutations in *Drosophila* Notch cause a notched wing tip.

Introduction

Proteolytic processing of membrane proteins is a vital component of cell–cell interactions. It is crucial for normal development and for healthy adulthood, but can also contribute to the pathogenesis of diseases such as cancer and rheumatoid arthritis (Blobel, 2005). This process, which is also referred to as protein ectodomain shedding (Figure 1), allows the release of growth factors and cytokines from their membrane anchors, and can activate or inactivate cell surface molecules or change their functional properties (Blobel, 2005). The regulated proteolytic release of a growth factor or cytokine from its membrane anchor fulfills a similar function as the regulated release of signaling molecules from a secretory vesicle: it allows storage of the growth factor and rapid and regulated release upon demand (Figure 2). A family of metalloproteinases called a disintegrin and metalloproteinase (ADAMs) because they contain a disintegrin and metalloproteinase domain (see domain organization in Figure 3) are key players in protein ectodomain shedding. Out of the approximately 30 ADAMs

found in mammalian genomes, ADAM17 and ADAM10 stand out for their essential roles in development (Blobel, 2005). ADAM17 is essential for activating the epidermal growth factor receptor (EGFR) during development (Peschon *et al.*, 1998; reviewed in Blobel, 2005) and is later required to maintain the skin and intestinal barrier in adults (Blaydon *et al.*, 2011; Franzke *et al.*, 2012; Chalaris *et al.*, 2010). In addition, ADAM17 regulates the release of the pro-inflammatory cytokine TNF α (Black *et al.*, 1997; Moss *et al.*, 1997), and thus has a role in TNF α -dependent diseases, including rheumatoid arthritis (Issuree *et al.*, 2013) and Crohn's disease (Chalaris *et al.*, 2010). The related ADAM10 is essential for the activation of the Notch signaling pathway (Rooke *et al.*, 1996; Hartmann *et al.*, 2002; Sotillos *et al.*, 1997), a pathway that is used to control a variety of cell fate decision during development and in adults (Kopan and Ilagan, 2009). Other ADAMs also have interesting functions, such as ADAM19, which is involved in heart valve development (Zhou *et al.*, 2004; Kurohara *et al.*, 2004), or ADAMs 9, 12, and 15, which are thought to have important roles in cancer (Peduto *et al.*, 2006, 2005; Najj *et al.*, 2008). However, since the functions of ADAM10 and 17 and the underlying mechanisms are currently better understood than those of other ADAMs, this article will focus on these two membrane-anchored metalloproteinases and highlight our understanding of their roles as key mediators of cell–cell interactions in development and disease.

Figure 1 Protein ectodomain shedding. The term 'protein ectodomain shedding' refers to the proteolytic release of membrane-anchored molecules from cell membranes. A membrane-anchored protease (green) is shown processing a membrane-anchored growth factor close to its membrane anchor, thereby releasing the soluble extracellular domain of the growth factor. Reproduced from Blobel, C.P., Carpenter, G., Freeman, M., 2009. The role of protease activity in ErbB biology. *Experimental Cell Research* 315, 671–682, Figure 1(A).

ADAM17, the TNF α Convertase

ADAM17 was first discovered in a search for molecules that regulate the release of the potent pro-inflammatory cytokine tumor necrosis factor α (TNF α) (Black *et al.*, 1997; Moss *et al.*, 1997). TNF α is considered to be the fire alarm of the body because it can help to activate an innate immune response, but TNF α can also cause damage to the body if its production and release is inappropriately activated, leading to autoimmune disease. TNF α is synthesized as a trimeric molecule in which each subunit is tethered to the cell surface through a membrane anchor (Figure 4(a)). These membrane tethers must be cut by the TNF α convertase (TACE, an alternative name for ADAM17) to release the soluble form of TNF α (Figure 4(b)), and therefore TACE/ADAM17 is considered a potential

Figure 2 Conceptual similarities between secretion from vesicles and ectodomain shedding of proteins. Regulated and constitutive secretion of proteins from intracellular vesicles that fuse with the plasma membrane is a well-established means of regulating cell–cell communications. Regulated and constitutive protein ectodomain shedding uses a very different mechanism, i.e., proteolysis, to accomplish something very similar. By cleaving the membrane tether of growth factors or cytokines in a regulated or constitutive manner, the proteases involved in protein ectodomain shedding, i.e., ADAM10 and ADAM17 and in some cases also other enzymes, can control the signaling via these molecules and thus their role in cell–cell interactions.

Figure 3 Domain Structure of an ADAM. ADAMs (a disintegrin and metalloprotease) are a family of membrane-anchored metalloproteinases that contain an N-terminal signal sequence and pro-domain (not shown), followed by a metalloprotease domain, a disintegrin domain that received this name because it is related to snake venom toxins called disintegrins, a cysteine-rich and EGF-like domain and a transmembrane domain followed by a cytoplasmic tail. Reproduced from Blobel, C.P., Carpenter, G., Freeman, M., 2009. The role of protease activity in ErbB biology. *Experimental Cell Research* 315, 671–682, Figure 1(B); Schlöndorff, J., Blobel, C.P., 1999. Metalloprotease-disintegrins: Modular proteins capable of promoting cell–cell interactions and triggering signals by protein–ectodomain shedding. *Journal of Cell Science* 112, 3603–3617, Figure 1, left panel, modified.

alternative target for treatment of diseases such as rheumatoid arthritis and Crohn's disease that depend on the release of soluble TNF α (Feldmann and Maini, 2008).

The typical mammalian genome contains over 500 proteases (Overall and Blobel, 2007), so once ADAM17 was identified as the TNF α convertase (Black *et al.*, 1997; Moss *et al.*, 1997), it was important to validate that it is indeed the physiologically relevant TNF α convertase and that none of the other proteases could take over its function if it is inactivated. The validation that ADAM17 is indeed the relevant TNF α convertase was accomplished using an assay that measures the function of soluble TNF α in mice. This assay, called endotoxin shock, relies on a rapid activation of the innate immune system by lipopolysaccharide (LPS, also called endotoxin), a component of the bacterial cell wall. Injection of LPS into mice can activate pattern recognition receptors (e.g., Toll-like receptor 4) to initiate the production and release of high levels of TNF α from myeloid cells, with eventually lethal consequences for the host (septic shock). Conditional knockout mice lacking ADAM17 in myeloid cells (immune cells that respond to LPS and produce TNF α) are protected from endotoxin shock and survive this challenge under conditions where wild type mice do not. Moreover, these conditional ADAM17 knockout mice have significantly lower levels of TNF α in their blood stream, corroborating that ADAM17 is the physiologically relevant TNF α convertase *in vivo*, and that no other protease in mice can effectively take over the release of TNF α in its absence (Horiuchi *et al.*, 2007).

ADAM17 is Crucial for EGFR Signaling

It is not uncommon for proteases and other biologically active molecules to have more than one major function, and this is

Figure 4 Protein ectodomain shedding of $\text{TNF}\alpha$ by ADAM17. The potent pro-inflammatory cytokine $\text{TNF}\alpha$ is generated as a trimeric molecule with three membrane tethers that must be cut by the $\text{TNF}\alpha$ -convertase (TACE, also referred to as ADAM17) to release the soluble form of $\text{TNF}\alpha$. Since the soluble form is thought to be responsible for autoimmune diseases such as Rheumatoid Arthritis (RA), ADAM17 is considered a potential target for treatment of RA.

also the case for ADAM17. This became evident when ADAM17 was completely inactivated in mice (knockout mice). The resulting ADAM17-deficient animals were born with open eyes and died shortly after birth (Peschon *et al.*, 1998), whereas normal wild type mice are born with closed eyes and survive. When genetically modified mice are born with open eyes, this is usually an indication of defects in the EGFR signaling pathway (Sibilia and Wagner, 1995) (although mutations in other pathways can also cause open eyes at birth). The EGFR is a cell surface tyrosine kinase receptor that is important for proper development of heart valves and for establishing a normal bone growth plate during mouse development. In adult mice and humans, a major role of the EGFR is thought to be the maintenance of the skin and intestinal barrier (see below, Jackson *et al.*, 2003; Sibilia *et al.*, 2003; Lichtenberger *et al.*, 2013). Moreover, inappropriate activation of the EGFR can lead to cancer, and therefore antibodies against the EGFR or drugs that block its kinase activity are used to treat EGFR-dependent cancers, such as colon cancer (Modjtahedi and Essapen, 2009; Wheeler *et al.*, 2010). An analysis of ADAM17 knockout mice revealed heart valve defects and abnormalities in the growth plate of the bone that closely resembled those observed in mice lacking the EGFR (Hall *et al.*, 2013; Jackson *et al.*, 2003), providing strong genetic evidence that ADAM17 has a key role in activating the EGFR signaling pathway.

Why is ADAM17 essential for the normal functioning of the EGFR tyrosine kinase receptor? The EGFR has 7 known ligands (EGFR-ligands), each of which is attached to the cell membrane via a membrane tether (Harris *et al.*, 2003). Unless the membrane tether is cut, EGFR-ligands cannot be released from cells to activate the EGFR (Blobel, 2005). ADAM17 is required for the shedding of several key EGFR-ligands, including transforming growth factor α ($\text{TGF}\alpha$), Heparin-binding epidermal growth factor (HB-EGF) and amphiregulin, which explains why inactivation of ADAM17 causes defects that closely resemble those seen in mice lacking the EGFR (Sahin *et al.*, 2004; Sunnarborg *et al.*, 2002) or HB-EGF (Jackson *et al.*, 2003), $\text{TGF}\alpha$ (Peschon *et al.*, 1998) or amphiregulin (Sternlicht *et al.*, 2005).

ADAM17-Dependent EGFR Activation Protects the Skin and Intestinal Barrier

Mouse models are commonly used to understand the function of specific molecules in the context of an intact organism *in vivo*. Because mice lacking ADAM17 die at birth with open eyes and heart valve defects (Jackson *et al.*, 2003; Peschon *et al.*, 1998), it was necessary to circumvent their postnatal lethality to gain better insights into the function of ADAM17 in adult animals. This was accomplished by generating 'hypomorphic' mice, so animals with strongly reduced activity of ADAM17 that was nevertheless sufficient for the mutant animals to survive (Chalaris *et al.*, 2010) or conditional knockout mice that allowed selective inactivation of ADAM17 in specific tissues in adult mice (Horiuchi *et al.*, 2007; Franzke *et al.*, 2012). These approaches revealed that a major function of ADAM17 is to protect the skin and intestinal barrier, most likely by activating the EGFR (Lichtenberger *et al.*, 2013). Activation of the EGFR is thought to control the production of enzymes called transglutaminases, which crosslink proteins in the skin, and presumably also in the intestine, thus ensuring proper barrier functions (Franzke *et al.*, 2012). How relevant are studies in mice for the understanding of human development and disease? The recent discovery of a patient lacking ADAM17 suggests that mouse models are highly relevant and informative in terms of understanding the function of the ADAM17/EGFR pathway in humans (Blaydon *et al.*, 2011). The ADAM17-deficient patient suffers from skin and intestinal inflammation that is in many ways very similar to the defects observed in ADAM17-deficient mice. This suggests that the skin and intestinal inflammation in the ADAM17-deficient patient can most likely be explained by inadequate activation of the EGFR, because there is no ADAM17-dependent EGFR-ligand shedding. Hopefully the information that has emerged from basic biomedical research on ADAM17 and its role in EGFR signaling using mouse models of disease will some day become useful for the treatment of ADAM17/EGFR-dependent cancers by inhibiting ADAM17 and thus the release of EGFR-ligands. On the other hand, these mechanistic studies might also help devise a custom-tailored treatment for

Figure 5 A model for transactivation of the EGFR/ERK1/2 signaling pathway by FGFR2b-dependent activation of ADAM17. Binding of FGF7 to the FGFR2b (1) stimulates ADAM17 in a manner that can be blocked by inhibitors of Src kinases, p38 MAP-kinase and of phosphatidylinositol 3 (PI3) kinase, which is responsible for the conversion of phosphatidylinositol 4,5-bisphosphate (PIP₂) to phosphatidylinositol 3,4,5-trisphosphate (PIP₃) (2). Stimulation of ADAM17 by FGF7 requires its transmembrane domain, but not the cytoplasmic domain. Activation of ADAM17 triggers release of the EGFR-ligand HB-EGF (3), which activates the EGFR (4) and ERK1/2 (5), thereby promoting FGF7-stimulated cell migration in keratinocytes. Both the FGFR2b and the EGFR are known to have critical roles in skin repair and inflammation of the skin. Reproduced from Maretzky, T., Evers, A., Zhou, W., *et al.*, 2011. Migration of growth factor-stimulated epithelial and endothelial cells depends on EGFR transactivation by ADAM17. *Nature Communications* 2, 229. doi:10.1038/ncomms1232, Figure 8, modified, with permission from Nature Publishing Group.

ADAM17-deficient patients, for example by applying soluble EGFR-ligands to replace the missing soluble growth factors and activate the EGFR.

ADAM17/TNF α and ADAM17/EGFR Signaling are Controlled by Upstream Regulators Called iRhoms

Protection of the skin and intestinal barrier by the ADAM17/EGFR pathway is a highly dynamic process that allows a rapid response to injury and precisely controlled activity for normal barrier maintenance. ADAM17-dependent activation of the EGFR can be very rapidly stimulated (within minutes) by a variety of different signaling pathways, including G-protein coupled receptors, tyrosine kinase receptors and even mechanical stress (Fischer *et al.*, 2003; Maretzky *et al.*, 2011). In keratinocytes, for example, the addition of keratinocyte growth factor activates ADAM17-dependent processing of EGFR-ligands, which in turn activates the EGFR signaling pathway and promotes cell migration (Maretzky *et al.*, 2011) (see Figure 5 for a diagram of this pathway, which is referred to as a triple membrane passing signal). How exactly is ADAM17 itself activated? Cell biological studies have demonstrated that the

transmembrane domain of ADAM17 is important for its rapid activation, whereas the cytoplasmic domain is not. The subsequent discovery of the seven-membrane spanning inactive Rhomboid-like protein 2 (iRhom2) as a binding partner of ADAM17 provided the first evidence for the existence of a molecule that could potentially regulate ADAM17 by interacting with its transmembrane domain (Adrain *et al.*, 2012; Maretzky *et al.*, 2013; McIlwain *et al.*, 2012) (see Figure 6 for a diagram of the putative interaction between iRhom2 and ADAM17).

iRhom2 and the related iRhom1 are similar to members of a family of intramembrane serine proteinases called Rhomboids, but lack the catalytic site and are therefore considered inactive Rhomboid-like proteins (hence the name iRhom) (Adrain and Freeman, 2012). Studies in knockout mice have shown that iRhom2 is critical for the function of ADAM17 in immune cells. Mice lacking iRhom2 have no mature ADAM17 in immune cells, and as a consequence, are protected from septic shock (no TNF α can be released) and inflammatory arthritis, a mouse model for rheumatoid arthritis, just like mice lacking ADAM17 in myeloid cells (McIlwain *et al.*, 2012; Issuree *et al.*, 2013). iRhom2-knockout mice are healthy and appear normal because the related iRhom1 can support the function and maturation of ADAM17 in all tissues except for

Model of putative interaction between ADAM17 and iRhomb2

Figure 6 Model of the interaction between iRhomb2 and ADAM17. ADAM17 is thought to be regulated by an interaction with the seven-membrane spanning molecule iRhomb2. This diagram shows a putative interaction between iRhomb2 and ADAM17, although it is important to emphasize that the exact nature of the interaction between these two molecules remains to be established. Reproduced from Blobel, C.P., 2005. ADAMs: Key players in EGFR-signaling, development and disease. *Nature Reviews Molecular Cell Biology* 6, 32–43, Figure 2, modified, with permission from Nature Publishing Group.

immune cells in these animals, where iRhomb1 is not expressed at high enough levels to support the maturation of ADAM17. However, when both iRhoms 1 and 2 are inactivated, then the function of ADAM17 appears to be completely lost. Therefore iRhomb1/2 double knockout resemble ADAM17 knockout mice or EGFR knockout mice in that they have open eyes at birth, heart valve defects and a defective bone growth plate (Blobel C, manuscript submitted). This strong genetic evidence for a role of iRhoms in regulating ADAM17-dependent EGFR signaling is further backed up by cell biological studies that show no mature ADAM17 and no activated EGFR in any cell type or tissue of iRhomb1/2 double knockout mice as well as no release of EGFR-ligands from iRhomb 1/2 knockout cells.

The EGFR signaling pathway also exists in the fruit fly *Drosophila melanogaster*, which has several EGFR-ligands (Spitz, Keren, and Gurken) that are also tethered to cells with a membrane anchor (Lee *et al.*, 2001). However, the protease that releases EGFR-ligands in *Drosophila* is actually an active Rhomboid, and thus an intramembrane serine proteinase (Urban *et al.*, 2001; Urban, 2002; Figure 7). So the release of EGFR-ligands is accomplished by a very different type of protease in flies and in mammals, where the metalloprotease ADAM17 is responsible for releasing EGFR-ligands (Blobel *et al.*, 2009), aided by the inactive Rhomboid-like iRhoms 1 and 2. Perhaps the identity of the protease responsible EGFR ligand-release changed during evolution because the iRhomb/ADAM17 complex allows a more rapid response to stimuli, and thus was perhaps better suited to protect and maintain the skin and intestinal barrier than the active Rhomboids that are used to process EGFR-ligands and activate the EGFR in flies.

ADAM10, A Crucial Regulator of Notch Signaling

ADAM10 is closely related to ADAM17, yet it has very different functions in that it is crucial for Notch signaling during

The EGFR signaling pathway is regulated by different proteases in flies and mammals

Figure 7 The EGFR pathway is regulated by different proteases in fruit flies and mammals. The main components of the EGFR pathway in *Drosophila melanogaster* are shown on the left. The intramembrane protease Rhomboid processes the EGFR-ligand Spitz (Spi, considered a functional equivalent of $\text{TGF}\alpha$ in mammals), allowing it to be released from the membrane of one cell in order to activate the EGFR on a second cell. In mammals, the EGFR-ligand $\text{TGF}\alpha$ is processed by a different protease, ADAM17, but with very similar consequences in that $\text{TGF}\alpha$ is released from its membrane anchor so that it can activate the EGFR on a different cell. The function of ADAM17 depends on the presence of iRhoms 1 or 2. The relationship between the active Rhomboid in flies and the inactive Rhomboid in mammals raises interesting questions about how and why the responsibility for cleaving EGFR-ligands was transferred from the Rhomboid in flies to the iRhomb1/2/ADAM17 complex in mammals during evolution. Since one of the main functions of the ADAM17/EGFR pathway in mammals is protection of the skin and intestinal barrier, it is tempting to speculate that the ability of the iRhomb1/2/ADAM17/EGFR pathway to rapidly respond to various stimuli, for example those released by injury, provided an evolutionary advantage that favored the mammalian proteolytic system to process EGFR-ligands. Reproduced from Blobel, C.P., Carpenter, G., Freeman, M., 2009. The role of protease activity in ErbB biology. *Experimental Cell Research* 315, 671–682, with permission from Nature Publishing Group.

development (Hartmann *et al.*, 2002; Rooke *et al.*, 1996; Sotillos *et al.*, 1997). Notch is a membrane-anchored transcriptional regulator that was initially discovered in *Drosophila*, where mutations in this gene resulted in a notched wing tip (Artavanis-Tsakonas *et al.*, 1995). Notch contains a large extracellular domain, a single transmembrane domain and an intracellular domain (Notch intracellular domain (NICD)) that can activate Notch-dependent transcription once it has entered the nucleus (Kopan and Ilagan, 2009; Figure 8). How does the membrane-anchored NICD manage to enter the nucleus? The answer is regulated intramembrane proteolysis, which consists of sequential proteolytic events that ultimately liberate the NICD from its membrane anchor (Kopan and Ilagan, 2009). First, Notch is processed by the pro-protein convertase furin during transit to the cell surface (referred to as S1 cleavage), but the actual regulatory step is the second processing event (S2 cleavage), which depends on ADAM10

Figure 8 Domain organization of Notch and its processing by three different enzymes. Notch is a membrane-anchored transcriptional regulator with a large extracellular domain, a transmembrane domain and an intracellular domain (NICD) that can be released from the membrane and enter the nucleus to activate Notch-dependent transcription. The approximate positions of the three major cleavage sites in Notch are shown: the Furin/pro-protein convertase-dependent S1 site, the ADAM10/Kuzbanian (KUZ)-dependent S2 site, and the S3 site, which depends on processing by the γ -secretase complex (only presenilin is shown as a seven-membrane spanning molecule, please note that the γ -secretase contains additional subunits that are not shown). Reproduced from Schlöndorff, J., Blobel, C.P., 1999. Metalloprotease-disintegrins: Modular proteins capable of promoting cell-cell interactions and triggering signals by protein-ectodomain shedding. *Journal of Cell Science* 112, 3603–3617, Figure 3, right panel, with permission from the Company of Biologists Ltd.

(also referred to as Kuzbanian, KUZ, see below) (Hartmann *et al.*, 2002; Rooke *et al.*, 1996; Sotillos *et al.*, 1997). The S2 cleavage event is closely followed by intramembrane processing through the protease presenilin/ γ -secretase (S3 cleavage, Figure 8), which releases the NICD from the membrane and allows it to enter the nucleus (De Strooper *et al.*, 1999; Kopan and Ilagan, 2009; Struhl and Greenwald, 1999).

ADAM10 was first identified as a major regulator of Notch signaling in *Drosophila* through the identification of a mutant in ADAM10 called Kuzbanian (Rooke *et al.*, 1996). A major function of Notch is to regulate cell fate decisions, and in the developing eye of fruit flies, it ensures that there is only one sensory bristle per ommatidium (a component of the compound eye of fruit flies and other insects). In the Kuzbanian (ADAM10) mutant, more than one sensory bristles developed (Rooke *et al.*, 1996), giving rise to abnormal cluster of sensory bristles that resembled the spiky hair of a character on the Muppets Show called Kuzbanian, hence the name (the Muppets Show was a television puppet show in the 1970s). Later the general relevance of this discovery in fruit flies for mammalian development was confirmed when knockout mice for

ADAM10 were found to resemble knockout mice for Notch (early embryonic lethality with characteristic defects in somitogenesis) (Hartmann *et al.*, 2002). Several additional studies using conditional knockout mice lacking ADAM10 in specific tissues also predominantly uncovered defects that resembled those seen upon inactivation of Notch in these tissues (Glomski *et al.*, 2011; Jorissen *et al.*, 2010; Weber *et al.*, 2011). Taken together, genetic studies in mice, fruit flies and worms strongly suggest that the principal purpose of ADAM10 is to regulate ligand-induced canonical Notch signaling (Hartmann *et al.*, 2002; Rooke *et al.*, 1996; Sotillos *et al.*, 1997; Wen *et al.*, 1997).

The processing of Notch is tightly regulated because the membrane proximal cleavage site for ADAM10 is protected and covered in the full length Notch receptor. This cleavage site is only exposed when a Notch ligand on an adjacent cell binds to Notch and thereby initiates endocytosis of Notch and its ligand. This process essentially provides the force to 'pull' a protective cap away from the cleavage site (Kovall and Blacklow, 2010; Tiyanont *et al.*, 2011; Figure 9). Once the cleavage site is exposed, it is rapidly processed by ADAM10 (Figures 9 and 10), allowing the presenilin complex to bind to the remaining stub and cleave within the transmembrane domain of Notch. Because presenilin is thought to be unable to process the intact Notch molecule, ligand binding to Notch followed by exposure and processing of the site for ADAM10 controls Notch signaling (Kopan and Ilagan, 2009; Kovall and Blacklow, 2010). Consequently, Notch signaling can be blocked by adding a soluble ligand that cannot exert an endocytic pull, or by inactivating ADAM10 (Hartmann *et al.*, 2002; Rooke *et al.*, 1996; Sotillos *et al.*, 1997) or presenilins (De Strooper *et al.*, 1999; Kopan and Ilagan, 2009). A diagram of the canonical Notch signaling pathway is shown in Figure 11.

In this context it is important to note that ADAM17 can also function as a Notch processing enzyme, but only under non-physiological conditions such as treatment of cells with the Ca⁺⁺-chelating agent EDTA (Brou *et al.*, 2000; Bozkulak and Weinmaster, 2009; van Tetering *et al.*, 2009). The negative regulatory repeats (NRR) covering the cleavage site for ADAM10 contain Ca⁺⁺ ions, and once these are removed by EDTA, the NRR unfolds, thereby exposing the cleavage site to ADAM17 (Kovall and Blacklow, 2010; Tiyanont *et al.*, 2011). In addition, ADAM17 can also contribute to processing of mutant forms of Notch carrying disruptions in the LNR repeats (Sulis *et al.*, 2011). However, genetic studies with flies and in mice support the view that ADAM10 is the major physiologically relevant Notch processing enzyme because inactivation of ADAM10 causes defects that resemble those seen upon inactivation of Notch, whereas inactivation of ADAM17 does not cause major defects in Notch signaling, but instead leads to inactivation of EGFR signaling and of the functions of soluble TNF α .

Other Substrates of ADAM10 and ADAM17

In addition to the main substrates of ADAM10 and ADAM17 discussed above (TNF α , EGFR-ligands, and Notch), both enzymes can also cleave a variety of other membrane proteins on the cell surface. Indeed, it is likely that most of the

Figure 9 Diagram of the ligand-dependent activation of Notch processing by exposure of the cleavage site for ADAM10. (1) Binding of a Notch ligand such as Delta triggers endocytosis of Delta, which in turn exerts a pull on Notch. The membrane proximal negative regulatory domains (NRR, pink) are shown covering the cleavage site for ADAM10. (2–4) As endocytosis of Notch and its ligand proceed, the resulting force pulls away the NRR, exposing the cleavage site for ADAM10, and thereby allowing the S2 processing to occur. S2 processing is rapidly followed by S3 processing by the γ -secretase, which allows the NICD to enter the nucleus (see [Figure 8](#)). Modified from Blacklow, S.C., Gordon, W.R., Arnett, K.L., 2008. The molecular logic of Notch signaling—a structural and biochemical perspective. *Journal of Cell Science*. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/18799787>, Figure 2(C).

Figure 10 Processing of Notch by ADAM10 once the NRR has been pulled away. A more detailed structural view of the diagram in [Figure 9](#) panel 4 shows the S2 cleavage site in Notch exposed to the active site of ADAM10. The beige domain surrounding the metalloprotease domain of ADAM10 represents its disintegrin domain and cysteine-rich region. The approximate position of the membrane and the membrane anchors for ADAM10 and Notch1 are shown. Modified from Blacklow, S.C., Gordon, W.R., Arnett, K.L., 2008. The molecular logic of Notch signaling – A structural and biochemical perspective. *Journal of Cell Science*. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/18799787>, Figure 2(D).

membrane-anchored molecules on cells can be shed by ADAM17, and in some cases by ADAM10, although the functional relevance of the majority of these processing events remains to be established. There are several examples of

membrane proteins shed by ADAM10 or ADAM17 that are not essential for development, but that make important contributions to human disease, including the low affinity IgE receptor CD23 ([Weskamp *et al.*, 2006](#)), which has important

Figure 11 The Canonical Notch signaling pathway. This diagrammatic representation of the Notch signaling pathway shows the Notch-ligand Delta attached to the 'signal sending cell' on the left. (1) Delta binds to Notch through the Notch extracellular Domain (NEC), triggering ligand and receptor endocytosis (see also Figure 9). (2) This exposes the S2 cleavage site for ADAM10, which in turn triggers intramembrane cleavage of Notch by the γ -secretase complex (3). This releases the Notch intracellular domain (NICD) from the membrane, allowing it to translocate to the nucleus (4) and activate Notch-dependent transcription (5). Modified from Blacklow, S.C., Gordon, W.R., Arnett, K.L., 2008. The molecular logic of Notch signaling—a structural and biochemical perspective. *Journal of Cell Science*. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/18799787>, Figure 1.

roles in asthma and allergic diseases, or the neutrophil cell adhesion molecule CD62L (L-selectin) (Li *et al.*, 2006), which is important for directing neutrophils to sites of inflammation. In addition, ADAM10 and potentially also ADAM17 are thought to have protective roles in Alzheimer's disease. A characteristic histopathological feature of brain sections from Alzheimer's disease patients is the presence of amyloid plaques (Selkoe, 1996; Figure 12). These contain large aggregates of a peptide that is called the amyloid beta peptide, which in turn is generated through proteolytic processing of a larger cell surface molecule that is called the amyloid precursor protein (Figures 13(a)–(d)). Similar to Notch, APP undergoes sequential cleavages, the first by an α -secretase (ADAM10 or ADAM17) or β -secretase (BACE), and the second by presenilin/ γ -secretase (Selkoe and Kopan, 2003). Processing of APP by the β -secretase and γ -secretase produces the A β peptide, which has a strong propensity to aggregate (Figures 13(b) and (c)), whereas processing of APP by α -secretase, i.e., ADAM10 (or ADAM17), gives rise to a shorter peptide that does not aggregate, and is therefore not amyloidogenic (Figure 13(d)). The α -secretase-dependent processing of APP preempts processing by beta secretase and is therefore considered to be protective. Attempts to block γ -secretase as a treatment for Alzheimer's disease have not been successful, in part because of toxicity of the inhibitory compounds, which also blocked Notch signaling. However, BACE remains a potential target for treatment of Alzheimer's disease (Vassar *et al.*, 1999), as does the possibility of selective activation of ADAM10 or ADAM17 in the brain (Fahrenholz and Postina, 2006), although much

remains to be learned about possible side effects associated with these potential treatments.

Summary

Taken together, ADAMs have emerged as crucial regulators of major signaling pathways with important roles in development and disease. All ligands of the EGFR must be cleaved in order to activate this receptor, which is important for maintenance of the skin and intestinal barrier, but can also promote cancer when it is inappropriately activated. ADAM17 together with iRhom1 and 2 control EGFR signaling in mammals and are thought to be able to allow rapid activation of this pathway if necessary, for example in case of an injury to the skin. In addition, the soluble form of the pro-inflammatory cytokine TNF α is generated from a membrane-anchored precursor by ADAM17 together with iRhom2. Moreover, ADAM10 is critical for signaling through the Notch receptor pathway. Notch receptors are membrane-anchored transcription factors that are processed by ADAM10 and then presenilin/ γ -secretase to release the Notch intracellular domain (NICD). This allows the NICD to enter the nucleus and promote Notch-dependent transcription, which is typically involved in cell fate decisions that control the proper development of an organism. Finally, ADAM10 and possibly also ADAM17 are thought to have an important protective role in Alzheimer's disease because they preempt the production of the A β peptide and thus help prevent the generation of amyloid plaques.

Figure 12 Diagrammatic representation of Amyloid plaques in the brain of an Alzheimer's disease patient compared to a normal brain without these plaques. <http://www.brightfocus.org/alzheimers/about/understanding/plaques-and-tangles.html>.

Figure 13 Diagram of the Amyloid Precursor Protein (APP) integrated into the cell membrane. (a) The APP molecule contains a large extracellular domain, a transmembrane domain and a short cytoplasmic domain (http://en.wikipedia.org/wiki/Alzheimer%27s_disease#mediaviewer/File: Amyloid_01big1.jpg). Panel (b) shows the processing of APP by β -secretase and γ -secretase, which releases the $\text{A}\beta$ peptide (highlighted in yellow) (http://en.wikipedia.org/wiki/Alzheimer%27s_disease#mediaviewer/File: Amyloid_02big1.jpg). (c) The $\text{A}\beta$ peptide is the main component of amyloid plaques (http://en.wikipedia.org/wiki/Alzheimer%27s_disease#mediaviewer/File: Amyloid_03big1.jpg). Panel (d) indicates the site of processing of APP by α -secretases (ADAM10 or ADAM17), which prevent processing by β -secretase, and are therefore considered to be protective in the context of Alzheimer's disease (http://en.wikipedia.org/wiki/Alzheimer%27s_disease#mediaviewer/File: Amyloid_01big1.jpg).

Extracellular: Plasma Membrane Proteases – Serine Proteases

TM Antalis and MS Buzza, University of Maryland School of Medicine, Baltimore, MD, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

Proteases constitute approximately 2% of the human proteome and are critically important for numerous biological processes such as blood coagulation, cell death, tissue morphogenesis, inflammation, and wound healing. Proteases are ubiquitously expressed and can be found secreted into the extracellular environment, anchored to the cell surface, in the cell cytosol or compartmentalized in cellular organelles such as lysosomes. Through cleavage of specific peptide bonds in proteins that are recognized as substrates, proteases mediate many cellular functions including protein degradation, enzymatic activation, and induction of cellular signaling (reviewed in Lopez-Otin and Bond, 2008). Serine proteases are one of the largest families of proteolytic enzymes, constituting over one third of all proteolytic enzymes, and are known to play critical roles in diverse biological functions including blood coagulation, digestion and tissue homeostasis. Serine proteases are defined by the classical histidine, aspartate, and serine amino acid residues which form their catalytic triad, that mediate the process of peptide hydrolysis. Peptide hydrolysis occurs when the nucleophilic serine residue in the enzyme's active site attacks the carbonyl moiety of the substrate peptide bond, forming an acyl intermediate, and proteolysis follows which also depends upon the histidine and aspartate residues of the enzyme (Hedstrom, 2002; Rawlings and Barrett, 2004). The S1A subfamily of serine proteases are the most widely studied group of serine proteases; the prototypical members being trypsin, chymotrypsin and thrombin, which are produced as soluble proteases that are secreted into the extracellular environment. In recent years, a unique sub-group of S1A serine proteases has been identified which are found to be directly anchored to the cell surface. This review focuses on the current knowledge and *in vivo* functions of this family of membrane-anchored serine proteases. Further information on this family of proteases can be found in the following comprehensive reviews: Antalis *et al.*, 2010; Bugge *et al.*, 2009; Hooper *et al.*, 2001; Netzel-Arnett *et al.*, 2003; Szabo and Bugge, 2011.

Membrane-Anchored Serine Proteases

To date, 20 human and 22 mouse membrane-anchored serine proteases have been identified, which are classified into 3 subclasses based on the manner in which they are anchored to the cell surface (Figure 1). These proteases are anchored to the plasma membrane either via a C-terminal glycosylphosphatidylinositol (GPI) linkage (GPI-anchored), a C-terminal transmembrane domain (Type I), or an N-terminal transmembrane domain (Type II). In addition to the extracellular serine protease domain which mediates catalytic activity, the type II transmembrane serine proteases (TTSPs), possess a stem region composed of various combinations of different

accessory domains localized adjacent to the cell surface and C-terminal to the serine protease domain (Figure 1; Antalis *et al.*, 2010; Bugge *et al.*, 2009; Netzel-Arnett *et al.*, 2003).

Catalytic Activity

The catalytic serine protease domains (SPD) are highly homologous, and are 225–230 amino acids in size. Being trypsin-like serine proteases, the membrane-anchored serine proteases all prefer to cleave peptide substrates after the basic amino acids arginine or lysine, and specificity is also influenced by the residues N- and C-terminal to the cleavage site. A comprehensive list of protein and peptide substrates cleaved by the membrane-anchored serine proteases *in vitro* is found in Antalis *et al.* (2010). Like other serine proteases, membrane-anchored serine proteases are synthesized as inactive pro-enzymes called zymogens. Proteolytic cleavage of the short N-terminal pro-peptide of the SPD is required to induce a conformationally active protease, with the cleaved pro-domain remaining attached to the protease domain by a disulfide linkage. This activation-inducing cleavage may be mediated by other serine proteases (membrane-anchored or soluble), that recognize the zymogen activation sequence of the protease as a substrate. An example of such a zymogen activation cascade is the activation of the GPI-anchored protease prostasin by the TTSP matriptase in skin (Netzel-Arnett *et al.*, 2006). Once activated, several membrane-anchored-serine proteases can also induce zymogen activation of serine proteases of the digestive, coagulation, and fibrinolytic systems (reviewed in Antalis *et al.*, 2010). In addition, several of the TTSPs are thought to be capable of auto-activation (Oberst *et al.*, 2003b; Velasco *et al.*, 2002). In these cases the amino acid sequence of zymogen activation site of the protease resembles the substrate specificity of the protease, and pro-domain cleavage is thought to occur due to a low level of catalytic activity of the protease zymogen.

Stem Region Accessory Domains

While the functions of the modular domains found in the stem regions of TTSPs are mostly uncharacterized, they are thought to contribute to the cell surface localization, substrate recognition or activation of the protease. Specific mutations in these domains have been described to occur in human diseases (Antalis *et al.*, 2010). The sea urchin sperm protein (SEA)-domain appears to be important for inducing protease activation in matriptase and matriptase-2, and undergoes a spontaneous conformational non-enzymatic cleavage event required for protease activity (Oberst *et al.*, 2003b; Ramsay *et al.*, 2009). In addition, the low density lipoprotein-receptor class A-like (LDLRA) domain of matriptase-2 appears important for cell surface expression (Silvestri *et al.*, 2009), and the frizzled and LDLRA domains of corin are important for macromolecular substrate recognition (Knappe *et al.*, 2004).

Figure 1 The membrane-anchored serine protease family. The human GPI-anchored serine proteases are prostatic and testisin. Trypsin $\gamma 1$ is the only known human type I transmembrane serine protease. The type II transmembrane serine proteases (TTSP) may be divided into four subfamilies: (1) the human airway trypsin-like protease/differentially expressed in squamous cell carcinoma (HAT/DESC) subfamily for which the stem regions are all composed of a single SEA-domain, (2) the hepsin/transmembrane protease, serine (TMPRSS) subfamily, each of which have a group A scavenger receptor domain (SRCR) in their stem region, that may be preceded by a single LDL receptor class A-like (LDLRA) domain or in enteropeptidase, an array of SEA, LDLRA, CUB, and MAM domains, (3) the matriptase subfamily, each containing a SEA-domain, two CUB domains, and 3-4 LDLRA domains in their stem region. Polyserase-1 comprises two active, and one catalytically inactive serine protease domains and a stem region containing an LDLRA domain, and (4) the corin subfamily, consisting of a single member, corin, which possesses a complex stem region composed of two frizzled domains, eight LDLRA domains, and one SRCR domain. NH₂ indicates amino terminus and C indicates carboxyl terminus. Adapted from Antalis, T.M., Buzza, M.S., Hodge, K.M., Hooper, J.D., Netzel-Arnett, S., 2010. The cutting edge membrane-anchored serine protease activities in the pericellular microenvironment. *Biochemical Journal* 428 (3), 325–346 and Bugge, T.H., Antalis, T.M., Wu, Q., 2009. Type II transmembrane serine proteases. *Journal of Biological Chemistry* 284 (35), 23177–23181.

Inhibition

After activation, the protease activity of membrane-anchored serine proteases can be regulated by interactions with endogenous protease inhibitors including membrane-anchored Kunitz-type inhibitors which form a reversible inhibitory complex with the protease. The Kunitz-type inhibitors HAI-1/SPINT1 and HAI-2/SPINT2 have been shown to regulate the activity of both matriptase and prostatic in *murine* models (Szabo *et al.*, 2007, 2009a,b, 2012). *In vitro*, the protease activities of several membrane-anchored serine proteases can also be inhibited by various members of the serpin superfamily, which form irreversible covalent complexes with serine proteases (reviewed in Antalis *et al.*, 2010). Inhibitory complexes between matriptase and anti-thrombin III (serpinC1), $\alpha 1$ -

proteinase inhibitor (serpinA1) and $\alpha 2$ -antiplasmin (serpinF2) have been detected in breast milk, suggesting an inhibitory role for these serpins *in vivo* (Tseng *et al.*, 2008).

While there is still much to learn about the physiological functions of individual members of this family, the development of murine models that are deficient in these proteases, and human diseases where expression or activity is reduced, have provided valuable evidence for the critical importance of many of these proteases in key biological functions as described below, and summarized in Tables 1 and 2.

The GPI-Anchored Serine Proteases

The two human GPI-anchored-membrane-anchored serine proteases, prostatic and testisin, are structurally the most

Table 1 Membrane-anchored serine proteases – physiological functions learnt through protease deficiency

Protease	Function	Implicated substrate	References
GPI-anchored Prostasin	Maintenance of epidermal barrier function	Unknown	(Frateschi <i>et al.</i> , 2012; Leyvraz <i>et al.</i> , 2005; Peters <i>et al.</i> , 2014)
	Regulation of ENaC-mediated fluid clearance in lung and colon epithelium	ENaC- γ subunit	(Frateschi <i>et al.</i> , 2012; Malsure <i>et al.</i> , 2014; Planes <i>et al.</i> , 2010)
	Regulation of hepatic insulin sensitivity by cleavage and inactivation of TLR-4	Toll-like receptor-4 (TLR-4)	(Uchimura <i>et al.</i> , 2014)
Testisin	Involved in sperm cell maturation and fertilizing ability	Unknown	(Aimes <i>et al.</i> , 2003; Inoue <i>et al.</i> , 1998; Netzel-Arnett <i>et al.</i> , 2009; Yamashita <i>et al.</i> , 2008)
Type II HAT/DESC subfamily			
HAT	Unknown. Not required for development, long-term health or survival in mice	Unknown	(Bertram <i>et al.</i> , 2012; Iwakiri <i>et al.</i> , 2004; Takahashi <i>et al.</i> , 2001; Yamaoka <i>et al.</i> , 1998)
HATL-1	Unknown. Not required for development, long-term health or survival in mice	Unknown	(Faller <i>et al.</i> , 2014; Kam <i>et al.</i> , 2009; Sales <i>et al.</i> , 2011)
Hepsin/TMPRSS subfamily			
Hepsin	Important for hearing in mice, where it has a role in cochlear development in inner ear	Unknown	(Faller <i>et al.</i> , 2014; Guipponi <i>et al.</i> , 2007; Kurachi <i>et al.</i> , 1994; Tsuji <i>et al.</i> , 1991)
	Maintenance of liver structural homeostasis in mice	Pro-HGF	(Hsu <i>et al.</i> , 2012)
TMPRSS2	Unknown. Not required for development, long-term health, fertility or survival in mice	Unknown	(Faller <i>et al.</i> , 2014; Jacquinet <i>et al.</i> , 2001; Kim <i>et al.</i> , 2006)
TMPRSS3	Mediates normal hearing in humans. Shown to be critical for cochlear hair cell survival in murine model of deficiency	Unknown	(Fasquelle <i>et al.</i> , 2011; Guipponi <i>et al.</i> , 2008; Lee <i>et al.</i> , 2013; Molina <i>et al.</i> , 2013)
TMPRSS5	Mediates normal hearing in humans	Unknown	(Guipponi <i>et al.</i> , 2008; Yamaguchi <i>et al.</i> , 2002)
Enteropeptidase	Critical for digestion of dietary proteins. Initiates a proteolytic cascade that results in the activation of several intestinal proteases	Trypsinogen	(Haworth <i>et al.</i> , 1971; Zheng <i>et al.</i> , 2009)
Matriptase subfamily			
Matriptase	Global role in maintenance of epidermal and epithelial barrier function and homeostasis.	Unknown	(List <i>et al.</i> , 2002, 2009; Yin <i>et al.</i> , 2014)
Matriptase-2	Essential regulator of iron homeostasis that prevents iron deficiency anemia	Hemojuvelin	(Du <i>et al.</i> , 2008; Folgueras <i>et al.</i> , 2008; Truksa <i>et al.</i> , 2009)
Corin subfamily			
Corin	Regulates systemic salt and water balance to prevent hypertension and cardiac hypertrophy	Pro-ANP, pro-BNP	(Chan <i>et al.</i> , 2005; Rame <i>et al.</i> , 2009; Wang <i>et al.</i> , 2008)

simple of this family, being composed solely of an N-terminal SPD, that is linked to the cell surface through a GPI moiety that is added to the C-terminus post-transcriptionally (Chen *et al.*, 2001; Hooper *et al.*, 1999; Figure 1). This lipid anchor is known to compartmentalize these proteases to specialized cholesterol-rich microdomains of the plasma membrane known as lipid rafts (Honda *et al.*, 2002; Verghese *et al.*, 2006). Prostasin, also known as PRSS8 and channel activating protease (CAP)-1, is found ubiquitously expressed in all epithelia (List *et al.*, 2007b). In polarized epithelia such as the gastrointestinal tract and kidney, it specifically localizes to the apical (luminal) membrane (Selzer-Plon *et al.*, 2009; Steensgaard *et al.*, 2010; Verghese *et al.*, 2006). Soluble forms of prostasin have been identified in both human seminal fluid and urine

(Koda *et al.*, 2009; Yu *et al.*, 1994), with release from the cell surface shown to be mediated by endogenous phospholipases or by proteolytic shedding (Iwashita *et al.*, 2003; Verghese *et al.*, 2006). Functionally, prostasin was the first identified membrane-anchored serine protease shown to enhance the activity of epithelial sodium channels (ENaC) by cleavage of the ENaC γ subunit to release an inhibitory peptide (Bruns *et al.*, 2007; Carattino *et al.*, 2008). ENaC activity is important for regulating sodium and water flux across polarized epithelium, and *in vivo*, increased expression or activity of prostasin, and the associated induction of ENaC activation, may be pathologically significant in increased fluid secretion in cystic fibrosis, high blood pressure and congenital sodium diarrhea (Table 2).

Table 2 Membrane-anchored serine proteases – roles in human disease

<i>Protease</i>	<i>Abnormality</i>	<i>Role in disease</i>	<i>References</i>
Prostasin	Over-expressed in lung epithelium of cystic fibrosis patients	May contribute to pathogenesis of cystic fibrosis by increasing fluid clearance	(Myerburg <i>et al.</i> , 2008; Planes <i>et al.</i> , 2010)
	Increased soluble prostasin detect in urine in hypertensive patients	May have a role in development of high blood pressure	(Maekawa <i>et al.</i> , 2009; Zhu <i>et al.</i> , 2008)
	Over-activity in colonic epithelium caused by loss of inhibitor function	Implicated role in fluid secretion in congenital sodium diarrhea	(Faller <i>et al.</i> , 2014)
Testisin	Aberrant expression in advanced stage ovarian cancer	May promote tumor growth and metastasis	(Shigemasa <i>et al.</i> , 2000; Tang <i>et al.</i> , 2005)
HAT	Lost in male germ cell tumors	Unknown	(Kempkensteffen <i>et al.</i> , 2006)
	Increased expression and shedding into airway fluids	Occurs in patients with inflammatory airway diseases such as asthma, function is unknown	(Yasuoka <i>et al.</i> , 1997)
DESC1	Lost in head and neck squamous cell carcinoma	Unknown	(Lang and Schuller, 2001; Sedghizadeh <i>et al.</i> , 2006)
HATL-5	Significantly decreased in cervical, esophageal, and head and neck carcinomas	Unknown	(Miller <i>et al.</i> , 2014)
Hepsin	Increased expression in human prostate cancers which correlates with disease severity	Increases prostate cancer progression and metastasis in mouse models	(Wu and Parry, 2007)
TMPRSS2	Frequent gene fusions between the promotor of TMPRSS2 and the ERG protooncogene and related transcription factors in prostate cancers	Androgen responsive elements in TMPRSS2 promotor drive expression of ERG transcription factor to promote prostate cancer progression	(Tomlins <i>et al.</i> , 2005; Yu <i>et al.</i> , 2010)
TMPRSS3	Point mutations that inhibit TMPRSS3 auto-activation blocking its activity	Causes non-syndromic autosomal recessive deafness	(Lee <i>et al.</i> , 2003; Scott <i>et al.</i> , 2001; Wattenhofer <i>et al.</i> , 2002)
TMPRSS4	Over-expressed in epithelial carcinomas of diverse origins	May have a role in tumor progression	(Choi <i>et al.</i> , 2008)
TMPRSS5	Point mutation that inactivates TMPRSS5	Associated with human deafness	(Guipponi <i>et al.</i> , 2008)
Enteropeptidase	Intestinal deficiency caused by point mutations	Failure to thrive due to reduced digestive function	(Holzinger <i>et al.</i> , 2002)
Matriptase	Mutations resulting in an inactive protease	ARIH, a rare human skin disease with ichthyosis and hair follicle defects	(Avrahami <i>et al.</i> , 2008; Basel-Vanagaite <i>et al.</i> , 2007; Desilets <i>et al.</i> , 2008; Lee <i>et al.</i> , 2007)
	Expression downregulated in inflammatory bowel diseases	May contribute to loss of intestinal barrier function and disease pathogenesis	(Kosa <i>et al.</i> , 2012; Netzel-Arnett <i>et al.</i> , 2012)
	Reduced expression in salivary gland epithelium	Causes loss of secretory cell function, contribute to pathogenesis of Sjogren's syndrome	(Yin <i>et al.</i> , 2014)
	Over-expressed in epithelial carcinomas of diverse origins	Possible role in tumor progression	(List, 2009)
Matriptase-2	Mutations that affect protease expression and activation	Causal factor in familial iron-refractory iron deficiency anemia	(Finberg <i>et al.</i> , 2008; Guillem <i>et al.</i> , 2008; Melis <i>et al.</i> , 2008)
Corin	Polymorphisms that cause reduced protease activity due to decreased zymogen activation	Associated with hypertension and cardiac hypertrophy, worse clinical outcome in patients with heart failure	(Dries <i>et al.</i> , 2005; Rame <i>et al.</i> , 2007, 2009; Wang <i>et al.</i> , 2008)
	Mutations and reduced expression and in pregnant uterus	May have causal role in the development of pre-eclampsia	(Cui <i>et al.</i> , 2012)

In mice, genetic deficiency of prostasin in the skin leads to complete loss of skin barrier function, which appears to be unrelated to defective ENaC activation (Frateschi *et al.*, 2012;

Leyvraz *et al.*, 2005; Peters *et al.*, 2014). The identification of prostasin's substrate in the epidermis remains uncertain, however, since genetic deficiency of the type II membrane-

anchored serine protease matriptase results in an identical epidermal defect (List *et al.*, 2002), it is thought that these proteases participate in a zymogen activation cascade that mediates epidermal barrier function. This is also supported by *in vitro* studies showing that expression of either protease is able to induce the activation of the other (Buzza *et al.*, 2013; Netzel-Arnett *et al.*, 2006). Interestingly, one study using murine models suggests that prostasin may mediate skin barrier function by a mechanism that is independent of its catalytic activity (Peters *et al.*, 2014). Using a murine model of prostasin deficiency in the liver, Uchimura *et al.* found that prostasin regulates hepatic insulin signaling by the cleavage and inactivation of the cell surface toll-like receptor, TLR-4, which suppresses inflammatory signaling (Uchimura *et al.*, 2014).

Testisin (also known as ESP-1 and PRSS21), in contrast to prostasin, exhibits an extremely specific and restricted tissue distribution, being abundantly expressed solely in male germ cells and spermatocytes, with lower expression also identified in microvascular endothelial cells, and eosinophils (Aimes *et al.*, 2003; Inoue *et al.*, 1998; Yamashita *et al.*, 2008). Functionally testisin is important for sperm cell maturation and fertilizing ability in mice (Netzel-Arnett *et al.*, 2009; Yamashita *et al.*, 2008), although the physiological substrate that mediates this activity is unknown. Pathologically, the aberrant testisin expression found in lung cancers and advanced ovarian cancers may contribute to tumour progression (Shigemasa *et al.*, 2000; Tang *et al.*, 2005), and the consequences of its loss in male germ cell tumors remains to be determined.

The Type I Transmembrane Serine Proteases

Tryptase $\gamma 1$ (also known as PRSS31, transmembrane tryptase and transmembrane protease γ -1) is found only in hematopoietic cells and is stored as the major component of mast cell secretory granules (Caughey *et al.*, 2000; Wong *et al.*, 1999, 2002b). Upon mast cell degranulation, tryptase $\gamma 1$ is retained on the cell surface by its N-terminal transmembrane domain (Wong *et al.*, 2002a). The physiological function and substrates of tryptase $\gamma 1$ remain unknown, but it is speculated that it may play a role in pathogen host defense in the human airway, where mast cells are important for protection against bacterial infections (Wong *et al.*, 2002a). In an animal model of exogenous administration to the airway, tryptase $\gamma 1$ promoted airway hyperresponsiveness and induced the expression of interleukin-13 (IL-13) in bronchiolar lavage fluid (Wong *et al.*, 2002a), which is a key cytokine implicated in the pathogenesis of allergic asthma.

The Type II Transmembrane Serine Proteases

TTSPs are by far the largest group of membrane-anchored serine proteases, with 17 members in humans and 19 members in mice (Bugge *et al.*, 2009; Szabo *et al.*, 2003; Figure 1). All are anchored to the cell surface by a C-terminal transmembrane domain, and have been phylogenetically divided into 4 subfamilies: (1) the human airway trypsin-like (HAT)/differentially expressed in squamous cell carcinoma gene

(DESC) subfamily, (2) the hepsin/transmembrane protease, serine (TMPRSS) subfamily, (3) the matriptase subfamily, and (4) the corin subfamily. In comparison to the GPI-anchored and type I serine proteases, which are composed of essentially a SPD and membrane anchor, the TTSPs possess a stem region C-terminal to the protease domain, which is comprised of a variety of modular structural accessory domains (Figure 1), most of which are currently of unknown function, but which are likely to play roles in protease activation, localization, and substrate recognition (Bugge *et al.*, 2009).

The HAT/DESC Subfamily

This subfamily is composed of 5 members in humans; HAT, DESC-1, HAT like-1 (HATL-1), HATL-4 and HATL-5, with mice having two additional members HATL-2 and HATL-3. This subfamily is the simplest of the TTSPs, having just one modular SEA-domain in their stem region. The role of this domain in HAT/DESC protease function has not been determined, but in other TTSPs such as matriptase, this domain undergoes a spontaneous conformation-induced auto-processing event at a conserved glycine residue which is important for protease activation (Macao *et al.*, 2006; Oberst *et al.*, 2003b). As its name implies, HAT protease (also known as TMPRSS11D) is found predominantly expressed in the epithelium of the airways, where it was originally identified as a soluble form found in extracellular lung fluids of asthma patients (Takahashi *et al.*, 2001; Yamaoka *et al.*, 1998; Yasuoka *et al.*, 1997). The normal physiological function of HAT is unknown, and deletion of the gene in mice caused no phenotypical defects in development or long-term health under non-challenged conditions (Sales *et al.*, 2011). Pathologically, HAT is up-regulated in chronic airway diseases (Yamaoka *et al.*, 1998), and has been shown *in vitro* to increase cell proliferation, and modulate inflammatory processes including increasing mucin production and suppression of fibrin deposition in airway epithelial cultures, suggesting it may play a role in disease suppression (Liu *et al.*, 2013; Matsushima *et al.*, 2006; Yoshinaga *et al.*, 1998). *In vitro*, HAT has been shown to cleave the urokinase plasminogen activator receptor (uPAR) (Beaufort *et al.*, 2007) and protease activated receptor (PAR)-2 (Iwakiri *et al.*, 2004), although the *in vivo* relevance of these substrates remains to be demonstrated. Interestingly, HAT may play a role in the propagation and spread of human respiratory viruses. HAT has been shown to cleave and activate the influenza virus hemagglutinin (HA) glycoprotein (Baron *et al.*, 2013; Bertram *et al.*, 2010), and the severe acute respiratory syndrome (SARS) coronavirus spike protein (Bertram *et al.*, 2011), both of which are important for mediating host cell entry, suggesting that inhibition of HAT activity may be a good target for therapeutic intervention in these infections.

Little is known regarding the *in vivo* function of the other members of this subfamily, which are expressed predominantly in epithelial cells of various organs. DESC-1 (also known as TMPRSS11E) is expressed in the epidermis, prostate, testis, placenta, thymus, and the epithelium of the head and neck (Lang and Schuller, 2001; Sales *et al.*, 2011; Sedghizadeh *et al.*, 2006), where it was originally identified based on its loss of expression in head and neck squamous cell carcinomas (Sales

et al., 2011). HATL-1 (also known as TMPRSS11A) is most highly expressed in the esophagus and trachea (Faller *et al.*, 2014; Kam *et al.*, 2009), and like HAT, the HATL-1 null mouse shows no overt phenotype (Sales *et al.*, 2011). Similarly, this protease may mediate the spread of SARS-corona virus through cleavage of the viral host cell entry spike glycoprotein (Kam *et al.*, 2009). HATL-4 (also known as TMPRSS11F) mRNA is expressed in the esophagus and testis, with lower expression in the cervix, placenta, and trachea (Sales *et al.*, 2011). HATL-5 (also known as TMPRSS11B) displays a relatively restricted tissue expression profile, being expressed in the cervix, esophagus, and oral cavity, with lower expression in the kidney and testis (Miller *et al.*, 2014; Sales *et al.*, 2011). This protease is found expressed in the more differentiated epithelial cells of cervix, esophagus, and trachea (Miller *et al.*, 2014), and is lost in squamous cell carcinomas of these tissues.

The Hepsin/TMPRSS Subfamily

This subfamily is composed of seven members in humans and mice. Hepsin possesses only one additional domain in its stem region, a group A scavenger receptor domain. TMPRSS2, TMPRSS3, TMPRSS4, mosaic serine protease large-form (MSPL), and spinesin have an additional low density lipoprotein receptor class A (LDLA) domain N-terminal to the scavenger domain, while enteropeptidase is much more complex containing multiple other domains types (Figure 1). Hepsin (also known as TMPRSS1), is abundantly expressed in the liver, but is also found at lower levels in other tissues such as the kidney, stomach, prostate, thyroid, and inner ear (Guipponi *et al.*, 2007; Kurachi *et al.*, 1994; Tsuji *et al.*, 1991). Physiological functions for hepsin have been identified in both liver and inner ear using murine models. While hepsin deficient mice do not show any strong defects in development or fertility (Wu *et al.*, 1998), mice lacking hepsin expression have abnormal cochlear structure and are deaf (Guipponi *et al.*, 2007). The physiological substrate cleaved by hepsin to mediate cochlear development has not been determined, but hepsin-deficient mice also show significantly reduced levels of the thyroid hormone thyroxine (Guipponi *et al.*, 2007) which is known to be important for cochlear development. Any relevance of hepsin expression to human hearing is yet to be reported. Recent analysis of liver specific hepsin null mice show its expression is important for maintenance of the structural integrity of the liver, with knock-out livers showing increased hepatocyte size and narrowed liver sinusoids (Hsu *et al.*, 2012). These authors demonstrated that the likely *in vivo* substrate cleaved by hepsin to regulate liver physiology is pro-hepatocyte growth factor (pro-HGF), a growth factor shown to be a substrate of hepsin *in vitro* (Kirchhofer *et al.*, 2005). Of importance, treatment of liver specific hepsin null mice with the active form of HGF was able rescue these phenotypic defects (Hsu *et al.*, 2012).

TMPRSS2 (also known as epitheliasin) is expressed in the epithelium of many tissues including the prostate, gastrointestinal tract, breast, lung, kidney, pancreas, ovary, lung, and salivary gland (Faller *et al.*, 2014; Jacquinet *et al.*, 2001). TMPRSS2 is of unknown function and is not required for

normal development or health in mice (Kim *et al.*, 2006). Similar to HAT, TMPRSS2 may augment virus entry into airway epithelium increasing virus propagation by cleaving the HA protein of influenza A virus (IAV) (Hatesuer *et al.*, 2013; Sakai *et al.*, 2014), and the SARS coronavirus spike protein (Heurich *et al.*, 2014). Of note, TMPRSS2 deficient mice are highly resistant to experimental IAV virus challenges (H1N1, H3N2, and H7N9 strains), which is associated with reduced HA cleavage *in vivo*, suggesting TMPRSS2 is a key host protease important for IAV infection and may represent a new therapeutic target in humans (Hatesuer *et al.*, 2013; Sakai *et al.*, 2014). TMPRSS3 (also known as TADG-12), is also expressed in epithelium of a variety of tissues where its function is unknown, however, its expression in the cochlea of the inner ear has been shown to be critically important for hearing in both humans and mice. At least five different point mutations in TMPRSS3 gene that affect protease activity have been linked to autosomal recessive deafness in humans (Guipponi *et al.*, 2008; Lee *et al.*, 2013; Scott *et al.*, 2001; Wattenhofer *et al.*, 2002). Furthermore, mice with TMPRSS3 deficiency are deaf, with reduced cochlear hair cell survival at the onset of hearing (Fasquelle *et al.*, 2011). The identification of the substrate cleaved by TMPRSS3 to mediate hearing is unknown, but expression of hair cell KCNMA1 potassium channels is reduced in mice with mutated TMPRSS3 (Molina *et al.*, 2013), suggesting a role in the acquisition of mature ion channels during cochlear development. Little is known about the biological function of TMPRSS4, also known as CAP-2 for its ability to activate ENaCs *in vitro* (Andreassen *et al.*, 2006; Passero *et al.*, 2012). However, it is over-expressed in a variety of epithelial carcinomas where it is correlated with disease progression and predicts poor patient survival (reviewed in Choi *et al.*, 2008). *In vitro* studies suggest TMPRSS4 mediates cancer cell invasion, epithelial-mesenchymal transition, and metastasis (Huang *et al.*, 2014; Kim *et al.*, 2010; Min *et al.*, 2014), where TMPRSS4 proteolytic activation of urokinase plasminogen activator (uPA) may be involved (Min *et al.*, 2014). TMPRSS5 (also known as spinesin), has an unusual expression pattern in comparison to other family members, being highly expressed in the brain and spinal cord (Yamaguchi *et al.*, 2002), where its function is unknown. TMPRSS5 is also expressed in the inner ear, and may be important for human hearing (Guipponi *et al.*, 2008). MSPL (also known as TMPRSS13) is expressed in the lung, placenta, prostate, and pancreas (Kim *et al.*, 2001) where its physiological function is unknown. Similar to HAT and TMPRSS2, it may play a role in influenza virus infection through cleavage of HA (Okumura *et al.*, 2010). Enteropeptidase (commonly known as enterokinase, also known as PRSS7) is expressed in upper small intestine (duodenum and jejunum) on the brush border of enterocytes of the intestinal villus (Hermon-Taylor *et al.*, 1977; Kitamoto *et al.*, 1994, 1995; Yuan *et al.*, 1998). Enteropeptidase has long been known to play a critical role in human digestion by activating a proteolytic cascade that results in the activation of numerous proteases important for human digestion (reviewed in Zheng *et al.*, 2009). Enteropeptidase cleaves and activates pancreatic trypsinogen to trypsin, which in turn activates other digestive zymogens such as chymotrypsinogen, proelastase, procarboxypeptidase, and prolipase in the lumen of the gut (Kunitz, 1939). Mutations that lead to truncated forms of the protease

that lack the active site are shown to cause malabsorption and failure to thrive in infants (Holzinger *et al.*, 2002).

The Matriptase Subfamily

This TTSP subfamily has four members – matriptase, matriptase-2, matriptase-3, and polyserase-1, which contain various combinations of accessory domains in their stem regions (Figure 1). Matriptase (also known as PRSS14, MT-SP1, CAP3, epithin, ST14) is the most well characterized of this subfamily and is found widely expressed in all epithelia (List *et al.*, 2006; Oberst *et al.*, 2003a). Matriptase has been shown to be critical for epithelial barrier function using mouse models of matriptase deficiency (List *et al.*, 2002, 2009). In humans, mutations affecting matriptase's enzymatic activity present with a rare form of skin disease (Basel-Vanagaite *et al.*, 2007; ARIH, see Table 2), which is characterized by scaly, itchy skin with increased permeability, similar to the phenotype of matriptase null mice (List *et al.*, 2002, 2007a). The substrate(s) cleaved by matriptase in the regulation of skin barrier function remain to be elucidated, although matriptase is thought to activate the pro-prostasin zymogen in this tissue (Netzel-Arnett *et al.*, 2006). In the polarized epithelium of the gastrointestinal tract where matriptase localizes to adherens junctions (Buzza *et al.*, 2010), matriptase is also critically important for regulating intestinal epithelial barrier function (Buzza *et al.*, 2010; List *et al.*, 2009), and mice deficient in intestinal matriptase develop chronic inflammation and spontaneous colitis-induced colon adenocarcinoma (Kosa *et al.*, 2012). In murine models, matriptase deficiency increases susceptibility to experimental colitis, and is found to be downregulated in human Crohn's disease and ulcerative colitis (Netzel-Arnett *et al.*, 2012). The matriptase substrate that regulates intestinal barrier function is unknown, but matriptase has been reported to induce an intracellular atypical protein kinase C signaling pathway that regulates the composition of the apical tight junctions (Buzza *et al.*, 2010). In the intestine and in contrast to the skin, prostasin appears to act upstream of matriptase and is important for inducing its activation in intestinal epithelium (Buzza *et al.*, 2013). There is also the possibility of a reciprocal zymogen activation cascade between these two proteases in different tissues, suggesting that both matriptase and prostasin zymogens may act as cofactors that can induce the activation of each other, in a mechanism that is independent of catalytic activity (Friis *et al.*, 2013). Matriptase is also lost in the salivary gland of patients with Sjogren's syndrome which exhibit salivary gland dysfunction and develop autoimmunity. Its loss may be important for disease pathogenesis, since matriptase deficiency in mice induces a primary Sjogren's syndrome-like phenotype with autoimmunity and loss of gland function (Yin *et al.*, 2014).

Matriptase also possesses strong oncogenic activities and in many epithelial cancers, its increased expression or activity (through loss of inhibition) is associated with disease progression (reviewed in List, 2009). Low level over-expression of matriptase in murine skin is sufficient to induce multistage carcinogenesis and invasive squamous cell carcinoma (List *et al.*, 2005). Based on murine models, the mechanism by which matriptase induces squamous cell carcinoma involves

cleavage and activation of the matriptase substrate pro-HGF (Lee *et al.*, 2000; Szabo *et al.*, 2011). *In vitro* studies also identified matriptase as the first membrane-anchored serine protease to activate the G-protein coupled receptor, PAR-2 (Camerer *et al.*, 2010; Takeuchi *et al.*, 2000). *In vivo* evidence suggests that cleavage of PAR-2, which induces inflammatory signaling pathways, may be an essential component for matriptase induced malignant progression of squamous cell carcinomas in animal models (Sales *et al.*, 2014). Matriptase activity in the skin also has been linked to the initiation of Netherton syndrome, which results from a loss of function mutation in the serine protease inhibitor LEKTI, which is important for regulating the activity of kallikrein proteases in the skin (Sales *et al.*, 2010). Genetic ablation of matriptase in mice deficient in the LEKTI inhibitor reduced inflammation, reduced aberrant protease activity and improved barrier function in the skin, suggesting matriptase is pathologically important in the human disease through kallikrein activation (Sales *et al.*, 2010).

Matriptase-2 (also known as TMPRSS6) is most highly expressed in the liver, but is also found in the kidney and uterine tissue (Hooper *et al.*, 2003; Velasco *et al.*, 2002). Matriptase-2 has a significant function in the regulation of iron metabolism. Humans with point mutations that affect matriptase-2 activity suffer from iron-refractory iron deficient anemia (Finberg *et al.*, 2008; Guillem *et al.*, 2008; Melis *et al.*, 2008), manifested by very low iron levels and severe microcytic anemia. Mice deficient in matriptase-2 expression also show this iron deficient phenotype (Du *et al.*, 2008; Truksa *et al.*, 2009). Matriptase-2 is thought to function by suppressing the expression of the liver hormone hepcidin which is known to be an important mediator of iron uptake by liver cells. This suppression occurs indirectly at the mRNA level, and is thought to be mediated by matriptase-2 cleavage of the bone morphogenetic protein (BMP) co-receptor hemojuvelin (Silvestri *et al.*, 2008, 2009; Truksa *et al.*, 2009), which has a role in activation of hepcidin transcription. Matriptase-3 (also known as TMPRSS7) is expressed in the brain, skin, salivary gland, and reproductive tissues (Szabo *et al.*, 2005); however, its physiological functions remain to be determined. Polyserase-1 (also known as TMPRSS9 and serase1B) is expressed in skeletal muscle, heart, kidney, liver, placenta, and brain (Cal *et al.*, 2003, 2007). This TTSP is highly unique in that it possesses 3 SPDs but its function is currently unknown.

The Corin Subfamily

Corin (also known as TMPRSS10) is the only member of this subfamily, and is unique in that it possesses two frizzled-like cysteine rich domains in its stem region, along with multiple LDLA domains and a scavenger domain (Figure 1). Corin is highly expressed in cardiomyocytes of the heart, but also in kidney, bone, brain, skin, and pregnant uterus (Hooper *et al.*, 2000; Yan *et al.*, 1999). Corin plays an important role in maintaining heart function and decreasing blood volume and blood pressure, by processing the cardiac hormone pro-atrial natriuretic peptide (pro-ANP) (Wu *et al.*, 2002; Yan *et al.*, 2000). Corin cleaves and activates pro-ANP to mature ANP which promotes natriuresis, diuresis, and vasodilation. In

humans, mutations in the corin gene which result in reduced activation and protease activity have been reported in patients with hypertension and cardiac hypertrophy, and are associated with a poorer prognosis in patients with heart failure (Dries *et al.*, 2005; Rame *et al.*, 2007, 2009; Wang *et al.*, 2008). Corin-deficient mice spontaneously develop salt-sensitive hypertension, cardiac hypertrophy and increased body weight, and possess an elevated level of pro-ANP and an absence of active ANP (Chan *et al.*, 2005; Nigrovic *et al.*, 2008). Corin and ANP have also been shown to be important for promoting placental trophoblast invasion and spiral artery remodeling in the pregnant uterus (Cui *et al.*, 2012). Pregnancy in corin- or ANP-deficient mice results in the development of high blood pressure and proteinuria, which are characteristics of pre-eclampsia. Interestingly, in human pre-eclamptic patients, uterine corin expression was found to be reduced, and several corin mutations which cause proteolytic activity were also identified in pre-eclamptic patients, suggesting defective corin may be pathologically important in this disease.

Conclusion

Following the sequencing of the human genome at the turn of the century and the discovery of the family of membrane-anchored serine proteases, these enzymes have emerged to play key roles in many diverse aspects of mammalian physiology. The misregulation of these enzymes is emerging to contribute to the pathology of a variety of diseases. The plasma membrane is a dynamic, fluid microenvironment where cell surface molecules act as cell sensors, initiating signals and relaying information. The extracellular SPDs contained in these molecules likely target specific cellular substrates, growth factors, receptors, and components of the extracellular matrix to modulate irreversible changes in the cellular environment. Clearly these unique enzymes represent potential strategic targets for diagnostic and therapeutic applications for a wide range of diseases.

Aspartic Proteases of Alzheimer's Disease: β - and γ -Secretases

MS Wolfe, Harvard Medical School, Boston, MA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Amyloid β -protein Small aggregation-prone proteolytic product that pathologically deposits in the Alzheimer brain.

AmEncyclopedia of Cell Biology
amyloid β -protein precursor A membrane protein that is proteolytically processed by β - and γ -secretases to produce the amyloid β -protein.

BACE1 Also β -secretase, a membrane protein and aspartic protease that cleaves APP to produce the $A\beta$ N-terminus.

Neuregulin A cell-surface receptor that undergoes proteolytic processing by β -secretase as a part of its signaling mechanism.

Notch A cell-surface receptor that undergoes proteolytic processing by γ -secretase as part of its signaling mechanism.

Presenilin A nine-transmembrane domain protein that serves as the catalytic component of the γ -secretase complex.

γ -Secretase A membrane-embedded aspartic protease complex that cleaves APP to produce the $A\beta$ C-terminus; comprised of presenilin, nicastrin, Aph-1, and Pen-2.

Amyloid and Alzheimer's Disease

Presentation and Pathology

Alzheimer's disease (AD) is a devastating progressive neurodegenerative disorder that initially presents as gradual loss of memory and executive function. On average, the disease runs its course over 8 years, but can be as long as 20 years, leading to severe disability and ultimately death. An estimated 5 million are affected in the United States and perhaps 20–30 million worldwide. As increasing age is the greatest risk factor for AD, longer lifespans in the developed world mean more cases of AD. Projections suggest that healthcare systems could be overwhelmed with the problem of AD in the coming decades. Understanding the molecular basis of the AD and leveraging that understanding to discover and develop effective disease-modifying therapeutics is of critical importance.

Two main pathological features are seen postmortem in the AD brain: amyloid plaques and neurofibrillary tangles (Goe-dert and Spillantini, 2006). The amyloid plaques are extracellular and composed primarily of the amyloid β -peptide ($A\beta$), a 38–43 amino acid amphipathic peptide. The

neurofibrillary tangles are intraneuronal and composed of filaments of the otherwise microtubule-associated protein tau. First identified by Alois Alzheimer in 1906, these two pathological features together now define the disease. For reasons that will be detailed later, pathological $A\beta$ is thought to precede and trigger pathological tau. Tau pathology can be found in the absence of amyloid plaques in other neurodegenerative brain diseases, and dominant missense mutations cause non-AD neurodegenerative diseases such as frontotemporal lobar degeneration and progressive supranuclear palsy. These and other findings suggest that a variety of insults, including pathological $A\beta$, can lead to tau pathology and neurodegeneration.

Amyloid Production

$A\beta$ is formed via proteolytic processing of the amyloid β -protein precursor (APP), a 695–770 amino acid type I integral membrane protein (Figure 1) (Tanzi and Bertram, 2005). First, β -secretase sheds the large extracellular/luminal ectodomain, leaving a 99-amino acid C-terminal fragment (CTF- β) in

Figure 1 Schematic of BACE1, APP and presenilin and proteolytic sites within APP leading to $A\beta$ production. APP is cleaved first by β -secretase – aka BACE1 – to release the ectodomain. Subsequent cleavage by γ -secretase within the APP TMD forms $A\beta$ (through proteolysis at the γ site) and AICD (through proteolysis at the ϵ site). BACE1 is a membrane-tethered aspartyl protease of the pepsin family (two catalytic aspartates in the ectodomain each labeled as D). Presenilin is the catalytic component of the γ -secretase complex, with two catalytic TMD aspartates. Upon assembly with the other members of the complex, presenilin undergoes autoproteolysis to NTF and CTF subunits to become active γ -secretase.

the membrane. APP CTF- β is then processed within its trans-membrane domain (TMD) by γ -secretase to release the APP intracellular domain (AICD) into the cytosol and A β into the lumen/extracellular space. Alternatively, APP can cleave 17 residues into the A β region by α -secretase to produce an 83-residue CTF- α that is subsequently processed by γ -secretase to release AICD and a truncated A β called p3. These proteolytic events occur normally (i.e., they are not solely pathological occurrences), and A β is secreted constitutively from most cell types, although primarily in neurons.

The normal biological function of APP and its proteolytic processing remains largely unknown (Wolfe and Guenette, 2007). Knockout of the single APP-like gene in flies results in only a mild behavioral phenotype. Knockout of APP in mice leads to impairment in spatial learning and neuronal long-term potential; however, double and triple knockouts with other APP family members (APP-like proteins 1 and 2) are lethal. These and other studies demonstrate that the APP proteins are functionally redundant, are critical to development, and play roles in neuronal cell adhesion and migration. Regarding APP proteolytic products, efforts to identify a true signaling role for AICD has been essentially fruitless. Recent evidence suggests that shed APP ectodomain may be essential to neuronal pruning via apoptosis during development (Nikolaev *et al.*, 2009). A β may be involved in neuronal function at normal physiological levels.

APP and Presenilin Mutations

In 1991, rare, dominantly inherited missense mutation in the APP gene were discovered to be associated with early-onset familial AD (FAD) (Chartier-Harlin *et al.*, 1991; Goate *et al.*, 1991), identical in presentation, progression and pathology to the much more common sporadic AD that strikes in old age. Over 30 such mutations have been found (alzforum.org/mutations), all in and around the small A β region of the large APP protein and to affect the amount or type of secreted A β peptides in ways that increased its aggregation propensity. Mutations near the β -secretase cleavage site increased formation of APP CTF- β and therefore all A β peptides. Mutations near the γ -secretase cleavage site increased the proportion of the much more aggregation-prone 42-residue A β (A β 42), a minor secreted A β variant – A β 40 is the major one – that represents the primary A β variant found in AD amyloid plaques. Mutations within the A β region itself increase the aggregation propensity of the peptide.

In 1995, the first mutations in the presenilin genes, presenilin-1 and -2 (PS1 and PS2) were discovered to be associated with FAD (Rogaev *et al.*, 1995; Sherrington *et al.*, 1995; Levy-Lahad *et al.*, 1995). Now well over 100 dominantly inherited missense mutations have been identified (alzforum.org/mutations), with some causing AD onset even in the third or fourth decade of life. Again, these FAD cases were identical to sporadic AD except for the early age of onset. The presenilins are membrane proteins with 9 TMDs (Laudon *et al.*, 2005; Oh and Turner, 2005; Figure 1), and unlike APP, their connection to AD was entirely unclear upon discovery. The closest known homolog was an obscure gene in *Caenorhabditis elegans* (*spe-4*) associated with spermatogenesis (L'hernault and

Arduengo, 1992). Other, closer worm homologs (*sel-12* and *hop-1*), however, were quickly discovered, and these were found to be involved in processes known to be connected to the Notch receptor, a key signaling molecule in developmental biology (Leviton and Greenwald, 1995; Li and Greenwald, 1997). Still, the connect to AD was completely unclear, until proteolysis of the Notch receptor TMD was found to be essential for Notch signaling to the nucleus (Schroeter *et al.*, 1998). This will be discussed further in the section on γ -secretase.

β -Secretase

Identification, Structure, and Mechanism

β -Secretase was discovered independently by four different groups in 1999–2000 (Vassar *et al.*, 1999; Sinha *et al.*, 1999; Yan *et al.*, 1999; Hussain *et al.*, 1999; Lin *et al.*, 2000), each of which approached the search differently (e.g., expression cloning, biochemical, and bioinformatic). The first report (Vassar *et al.*, 1999) dubbed the enzyme the β -site APP-cleaving protein (BACE), a name which has endured. A close homolog – BACE2 – was quickly discovered (Saunders *et al.*, 1999), with β -secretase then called BACE1. BACE1 is a membrane-tethered member of the pepsin family of aspartic proteases (Figure 1), and a cocrystal structure of the luminal/extracellular domain (no TMD) with a bound transition-state analog inhibitor quickly confirmed the characteristic juxtaposition and coordination of the two conserved aspartic acids required for catalysis (Hong *et al.*, 2000). The structure also revealed two lobes, with the peptidomimetic inhibitor bound at the interface (i.e., the active site is located at the interface between these two lobes). The cytosolic region of BACE1 is very short but contains an acidic cluster-dileucine motif important for subcellular trafficking (Huse *et al.*, 2000; He *et al.*, 2002, 2003).

BACE1 expression is fairly ubiquitous; however, high levels are found in the brain, explaining why this organ makes relatively large amounts of A β . The enzyme cleaves just before the Asp-1 position (A β numbering) within APP, but the FAD-causing Swedish double mutation Lys-Met $\rightarrow$ Asn-Leu at positions -2/-1 is cleaved much more effectively by BACE1 than wild-type APP (Citron *et al.*, 1992), explaining the elevated A β production from this mutant. Recently, an AD-protective mutation in APP with the opposite biochemical effect was discovered in an Icelandic population (Jonsson *et al.*, 2012). This mutation – Ala-2 to Thr – correlates with a decreased risk of AD and an increased retention of cognitive abilities even into old age, along with a decrease in cleavage by BACE1. BACE2 can also cleave APP, but it is poorly expressed in the brain (Bennett *et al.*, 2000) and its APP cleavage site is different from that of BACE1, 20–21 residues within the A β sequence (Farzan *et al.*, 2000).

Knockout Mice

Homozygous deletion of the BACE1 gene in mice resulted in healthy, viable and fertile animals, initially without obvious abnormalities (Cai *et al.*, 2001; Luo *et al.*, 2001). Crossing

these knockout mice with transgenic mice overexpressing human APP in the brain revealed the absence of brain A β production, strong evidence that BACE1 is the primary β -secretase. As the APP transgene contained the Swedish double mutation near the β -secretase cleavage site, some objection has been raised to whether BACE1 is indeed β -secretase, capable of cleaving wild-type APP (Hook *et al.*, 2008). However, BACE1 knockout mice also do not produce endogenous mouse A β from mouse APP (Nishitomi *et al.*, 2006), in which the sequence around the BACE1 cleavage site is conserved. Crossing BACE1 null mice with an AD mouse model expressing a human FAD APP transgene demonstrated the absence of BACE1 prevents cerebral plaque formation and rescues memory deficits seen in these models (Ohno *et al.*, 2004).

Later studies, however, revealed that complete elimination of BACE1 is not as harmless as originally thought. Knockout mice showed reduced synaptic function and plasticity and developed behavioral abnormalities resembling schizophrenia (Savonenko *et al.*, 2008). Moreover, the mice developed substantial loss of myelination of peripheral neuronal axons, due to decreased signaling from neuregulin (Willem *et al.*, 2006). These findings do not necessarily mean that BACE1 is a poor therapeutic target for AD, as proteolytic activity from BACE1 is absent from birth in these null mice. A better model for safety and efficacy with respect to AD would be a conditional knockdown or knockout in mature mice, to avoid developmental defects. Such mice have not yet been reported. Partial reduction of BACE1 may also be safe and sufficient (Mcconlogue *et al.*, 2007).

Other Substrates

After the discovery of BACE1, the search for substrates besides APP began. Early studies identified ST6Gal I, a membrane-bound sialyltransferase (Kitazume *et al.*, 2001). Cleavage by BACE1 results in secretion of the enzyme, thereby regulating its biological role. P-selectin glycoprotein ligand 1, which mediates leukocyte adhesion in inflammatory reactions, was also shown to be a BACE1 substrate (Lichtenthaler *et al.*, 2003). The dramatic reduction in peripheral myelination in BACE1 null mice led to the finding that neuregulin-1 (NRG1) isoforms are also BACE1 substrates (Willem *et al.*, 2006), critical for NRG1 signaling and stimulation of myelination. As NRG1 signaling through its cognate receptor ErbB4 have been implicated in the etiology of schizophrenia, deficient NRG1-ErbB4 signaling may lead to the schizophrenia-like behavioral phenotype in BACE1 knockout mice (Savonenko *et al.*, 2008). These findings have raised concerns about the safety of BACE1 inhibitors as AD therapeutics. Again though, these deficiencies are seen upon complete knockout of BACE1 from conception onward and may not be an indication of safety upon partial inhibition in aging adults.

An unbiased proteomic analysis revealed dozens of putative substrates for BACE1 identified in human HEK293 embryonic kidney cells and HeLa cervical carcinoma cells, both overexpressing BACE1 (Hemming *et al.*, 2009). Many of these substrates were also validated in cell culture. Surprisingly, a clear consensus sequence was not seen, emphasizing the importance of taking an unbiased approach. Almost all of the

substrates were type I integral membrane proteins, although one was type II and three were glycosphosphatidylinositol (GPI)-anchored. The biological roles of these various BACE1-mediated proteolytic events remains largely unclear, although many of these substrates are receptors or are involved in cell-cell contact. Two more recent proteomics studies employed neurons and without overexpression (Zhou *et al.*, 2012; Kuhn *et al.*, 2012), making the physiological relevance of the findings more likely. Among the more interesting validated substrates were the neuronal cell adhesion molecules (NCAMs) L1 and CHL1, both of which localize to synapses and may affect plasticity.

Inhibitors

The first designed BACE1 inhibitors were substrate-based peptidomimetics containing a hydroxyethylene moiety that mimicked the transition-state of aspartyl protease catalysis (Ghosh *et al.*, 2000). The compounds were highly potent, inhibiting BACE1 with K_i values at or below 1 nM. Various types of transition-state analog inhibitors of BACE1 were developed, and these helped define the side chain preferences for the active site pockets on the enzyme. Consistent with loose sequence specificity of substrates (Turner *et al.*, 2002; Gruninger-Leitch *et al.*, 2002), none of the active site pockets were found to be particularly specific, although some preferences could be determined. Co-crystallization of BACE1 with one of these inhibitors, which spanned the P4-P4' positions, provided important information about the nature of the active site and substrate recognition (Hong *et al.*, 2000). The active site was located between the two lobes of the protease, each contributing one conserved aspartate, and found to be relatively long and shallow. This explained the loss of potency upon shortening the peptidomimetic inhibitors. Moreover, the inhibitor was covered by a flap, a common feature found in other aspartyl proteases of the pepsin family.

Peptidomimetic inhibitors, however, typically do not make for useful drugs. This is particularly true for BACE1 inhibitors, as compounds must traverse the blood-brain barrier, in addition to being metabolically stable in the periphery. The large size required for potency of transition-state mimicking peptide analogs did not allow good transport into the brain in general. Thus, considerable efforts have gone into identifying small, nonpeptide inhibitors with good potency, specificity and drug-like *in vivo* properties (Ghosh and Osswald, 2014). Such inhibitors have been identified through screening of chemical scaffolds followed by optimization, often using structure-based design. Another strategy has been computational screening, which has provided initial hits for modification into potent inhibitors.

Prospects for Therapeutics

The structure of BACE1 bound to an inhibitor was first reported in 2000 (Hong *et al.*, 2000), but the development of orally bioavailable BACE1 inhibitors with the ability to lower brain A β has been difficult and slow (Ghosh and Osswald, 2014). The primary reasons for this are the characteristics of the BACE1 active site (long and shallow, making the

identification of small, nonpeptidic inhibitors challenging) and the fact that many compounds that inhibit BACE1 are substrates for P-glycoprotein (which leads to expulsion of the compounds from the brain if they do manage to get in) (Meredith *et al.*, 2008). Nevertheless, compounds that lowered brain A β upon oral administration in AD mouse models (e.g., Hussain *et al.*, 2007) and nonhuman primates (e.g., Sankaranarayanan *et al.*, 2009) eventually emerged, and several compounds have advanced into clinical trials in recent years.

Scientists at Eli Lilly discovered an aminothiazine, LY2811376, as a potent, orally bioavailable nonpeptidic inhibitor that lowered A β in the central nervous system (specifically in the cerebrospinal fluid (CSF)) in healthy volunteers, and the compound appeared to be safe and well tolerated (May *et al.*, 2011). However, while the candidate progressed in clinical trials, further evaluation in animals revealed serious retinal toxicity. Reports conflict on whether retinal pathology appears in BACE1 knockout mice (e.g., Cai *et al.*, 2012). However, inhibition of the related BACE2 cannot be ruled out, as the compound is only modestly selective for BACE1 over BACE2. Another aminothiazine, LY2866721, soon followed but was recently halted due to liver toxicity. The reasons for the liver toxicity are unclear, but do not appear to be an on-target effect. As of this writing, AstraZeneca is moving into advanced clinical trials with an amino-isindole AZD3839, which displayed safety and efficacy (in terms of lowering CSF A β), as has Merck's MK-8931 (undisclosed structure).

γ -Secretase

Identification and Mechanism

Soon after their discovery, dominant FAD-associated presenilin mutations were determined to increase the ratio of aggregation-prone A β 42 to A β 40, in transfected cell lines, transgenic mice, patient-derived human fibroblasts, and patient plasma samples (Borchelt *et al.*, 1996; Citron *et al.*, 1997; Tomita *et al.*, 1997; Xia *et al.*, 1997; Duff *et al.*, 1996; Scheuner *et al.*, 1996). These findings suggested that presenilin can modulate γ -secretase activity, directly or indirectly, to change the cleavage site specificity within the APP TMD. The presenilins were also found to assemble into higher molecular weight complexes (Capell *et al.*, 1998; Yu *et al.*, 1998) and to be cleaved into stable N-terminal and C-terminal fragments (NTFs and CTFs) in a regulated manner (Thinakaran *et al.*, 1996; Ratovitski *et al.*, 1997), suggesting that functional presenilin is an NTF/CTF heterodimer and part of a larger complex. Knockout of PS1 in mice is embryonic lethal (Shen *et al.*, 1997; Wong *et al.*, 1997); however, culturing of the embryonic fibroblasts revealed a dramatic reduction in γ -secretase activity (reduced A β production and elevation of APP CTFs) (De Strooper *et al.*, 1998). PS1/PS2 double knockout cells then demonstrated that presenilins are absolutely required for γ -secretase activity (Herreman *et al.*, 2000; Zhang *et al.*, 2000).

The specific role of presenilin, however, was unclear until the recognition that these proteins contain two completely conserved transmembrane aspartates, one in TMD6 and one in TMD7, that are essential for γ -secretase activity (Wolfe *et al.*,

1999b). This finding was consistent with the fact that substrate-based peptidomimetics containing aspartyl protease transition-state mimicking moieties could inhibit γ -secretase (Wolfe *et al.*, 1999a; Shearman *et al.*, 2000). Indeed, such active site-directed inhibitors bind directly to presenilin NTF and CTF (Li *et al.*, 2000a; Esler *et al.*, 2000), suggesting that the active site is at the interface between these two presenilin subunits, each of which contribute one of the two conserved and essential TMD aspartates. Presenilin is now known to be part of a larger family of membrane-embedded aspartyl protease (Wolfe, 2009), with no sequence resemblance to the pepsin family of soluble aspartyl proteases.

The factors regulating presenilin NTF/CTF formation were then discovered to be the other protein members of the higher molecular weight complex into which presenilin assembles (Takasugi *et al.*, 2003; Kimberly *et al.*, 2003; Edbauer *et al.*, 2003). Three transmembrane proteins, nicastrin, Pen-2 and Aph-1, are all necessary for γ -secretase activity, and these proteins along with presenilin are sufficient for this proteolytic activity as well. The four components assemble together in the ER (Capell *et al.*, 2005), whereupon presenilin is cleaved into NTF and CTF subunits, a process that also requires the two TMD presenilin aspartates (i.e., presenilin is a zymogen that undergoes autoproteolysis) (Wolfe *et al.*, 1999b; Fukumori *et al.*, 2010). While there had been some controversy over the size and stoichiometry of the complex, a rigorous analysis by co-immunoprecipitation established that only one of each component is required for γ -secretase activity (Sato *et al.*, 2007), and this finding was unambiguously confirmed by electron microscopic analysis of purified, active complexes (see below).

In recent years, evidence has mounted supporting a processive proteolysis mechanism for γ -secretase cleavage of APP. The first clue for such a mechanism came from the finding of discrepancies between the C-termini of secreted A β peptides and the N-termini of the AICD (Weidemann *et al.*, 2002) (see γ and ϵ cleavage sites in the APP TMD in Figure 1). Moreover, longer, membrane-associated forms of A β , ranging from 45–49 residues, were discovered, taking the A β sequence all the way to where AICD begins (Qi-Takahara *et al.*, 2005). These findings suggested that γ -secretase first cuts the APP TMD to release AICD and form A β 48 or A β 49; the long A β peptides are then trimming to secreted A β s (Funamoto *et al.*, 2004). Furthermore, the pattern of A β peptides produced suggested that the C-terminal trimming generally occurs every three or four amino acids, an idea supported by mass spectrometric detection of the expected tri- and tetrapeptide products (Takami *et al.*, 2009). Importantly, A β 42 is a precursor to A β 38, and this step can be stimulated by certain modulators of γ -secretase activity (Okochi *et al.*, 2013) (see later).

Other Substrates

The finding that presenilin deficiency in *C. elegans* resulted in a phenotype resembling that of Notch deficiency led to the discovery that the Notch receptor, like APP, is cleaved within its TMD by a presenilin-dependent γ -secretase-like activity and that this proteolysis is required for Notch signaling (Schroeter *et al.*, 1998; De Strooper *et al.*, 1999). Release of the Notch

intracellular domain from the membrane is followed by translocation to the nucleus, with binding and activation of (CBF-1, Suppressor of Hairless, Lag-2) CSL transcription factors. Notch signaling is involved in many cell differentiation events, its physiological role often tissue- and context-dependent (Kopan and Ilgan, 2009). Complete knockout of presenilins or other γ -secretase components in other animals besides worms also leads to a Notch-deficient and embryonic lethal phenotype, suggesting that cleavage of Notch is the most important role of γ -secretase in all metazoans.

Over the years, dozens of other substrates besides APP and Notch have been described, all of which are type I integral membrane proteins that undergo ectodomain shedding (Hemming *et al.*, 2008; Haapasalo and Kovacs, 2011). Some of these γ -secretase-mediated proteolytic events are part of signaling pathways, similar to Notch. These include N-cadherin, the intracellular domain of which interacts with transcriptional activator CBP (CREB binding protein), leading to translocation to the cytosol and degradation by the proteasome (Marambaud *et al.*, 2003); and ErbB4, the intracellular domain of which binds to repressors of astrocyte gene expression to inhibit astrocyte differentiation (Sardi *et al.*, 2006). However, many γ -secretase-generated products do not appear to have a signaling function, leading to the hypothesis that γ -secretase helps clear away membrane stubs left behind after ectodomain shedding (i.e., that γ -secretase is 'the proteasome of the membrane') (Kopan and Ilgan, 2004).

Inhibitors and Modulators

As with BACE1, the first γ -secretase inhibitors were substrate-based peptidomimetics. Design of peptides based on the cleavage sites within the APP TMD that lead to A β 40 or A β 42 with aspartyl protease transition-state mimicking moieties provided compounds that inhibited A β production and elevated APP CTF γ -secretase substrates in cell culture (Wolfe *et al.*, 1998, 1999a; Shearman *et al.*, 2000). Varying the hydrophobic side chains in these peptidomimetic transition-state analogs (e.g., Ala, Val, Ile, Leu, and Phe) typically did not substantially affect inhibitor potency, suggesting that the protease has large hydrophobic pockets that can accommodate these residues (Wolfe *et al.*, 1999a; Moore *et al.*, 2000; Esler *et al.*, 2004; Bakshi and Wolfe, 2004). As mentioned above, conversion of these types of active site-directed inhibitors into affinity labeling reagents led to the tagging of presenilin NTFs and CTFs (Li *et al.*, 2000b; Esler *et al.*, 2000). Moreover, immobilization of transition-state analog inhibitors allowed purification of the γ -secretase complex (Esler *et al.*, 2002; Kimberly *et al.*, 2003; Beher *et al.*, 2003).

Other peptide analog inhibitors include APP TMD-based peptides containing the helix-inducing aminoisobutyric acid, to better mimic the substrate conformation that initially interacts with the enzyme (Das *et al.*, 2003). Such compounds could be highly potent (Bihel *et al.*, 2004), and conversion to affinity labeling reagents led to tagging of presenilin NTFs and CTFs (Kornilova *et al.*, 2005), as with transition-state analog inhibitors. However, competition experiments demonstrated that the binding sites were distinct, suggesting the presence of an initial substrate docking site on the outer surface of

presenilin, at the NTF/CTF interface. These findings suggested that substrate TMDs first dock onto presenilin before passing between NTF and CTF to access the protease active site.

As with BACE1 inhibitors, nonpeptide γ -secretase inhibitors were sought to identify leads with better drug-like properties. Many such inhibitors have been described (Kreft *et al.*, 2009), some with very high potencies. Interestingly, upon conversion of these inhibitors into affinity labeling reagents, all those that have been so converted tag presenilin, either NTF, CTF or both. No other components of the protease complex are labeled by inhibitors. Despite this, nicastrin and Aph-1 have been implicated in substrate recognition along with presenilin (Shah *et al.*, 2005; Chen *et al.*, 2010).

Concern about Notch-based toxic consequences of γ -secretase inhibitors has led to two strategies for developing safe and effective therapeutics for AD that target the protease. The first is to identify so-called 'Notch-sparing' inhibitors (Imbimbo *et al.*, 2011). These compounds show varying degrees of selectivity (with some reports of no selectivity) for inhibiting the cleavage of APP over that of Notch by γ -secretase, apparently through interaction with an allosteric site on the enzyme (again, located on presenilin) (Crump *et al.*, 2012). The second strategy is to develop modulators of γ -secretase that lower A β 42 without inhibiting total A β peptide levels (Golde *et al.*, 2013). These compounds apparently work by enhancing the conversion of A β 42 to A β 38 (Okochi *et al.*, 2013). The therapeutic potential of γ -secretase inhibitors and modulators will be described later.

Toward Structure Elucidation

A high resolution structure of the γ -secretase complex has not yet been determined, undoubtedly due to the fact that the enzyme is composed of four different membrane proteins, and with likely heterogeneity in the glycosylation of nicastrin. Another limitation is that the protease has not yet been successfully reconstituted from separately expressed and purified components: the four proteins must be expressed together in a eukaryotic cell line prior to purification for structural studies. Nevertheless, a number of structures have been reported using electron microscopy (EM) and single-particle analysis (Lazarov *et al.*, 2006; Ogura *et al.*, 2006; Osenkowski *et al.*, 2009; Renzi *et al.*, 2011; Li *et al.*, 2014), including most recently a structure solved to 4.5 Å resolution (Lu *et al.*, 2014). Critical prerequisites for structure elucidation, however, were determination of the stoichiometry of the complex (one of each component) (Sato *et al.*, 2007) and determination of its size (~230 kDa, consistent with the 1:1:1:1 stoichiometry) (Osenkowski *et al.*, 2009). Also critical were prior elucidation of the membrane topologies of PS1 (Laudon *et al.*, 2005; Oh and Turner, 2005), Aph-1 (Fortna *et al.*, 2004) and Pen-2 (Crystal *et al.*, 2003) as well as the protein-protein contacts (e.g., Pen-2 with PS1 NTF, nicastrin with Aph-1, and PS1 CTF with either of these two partial complexes) (Fraering *et al.*, 2004; Steiner *et al.*, 2008). Cysteine scanning mutagenesis and use of water accessible crosslinking reagents has also proven useful in probing the catalytic pore of PS1 (Tolia *et al.*, 2006, 2008; Sato *et al.*, 2006, 2008; Takagi *et al.*, 2010).

Earlier EM studies, with resolutions of 12 Å at best, revealed relatively featureless globular structures. However, several characteristics could be gleaned. The location of the nicastrin ectodomain was determined using lectins or antibodies, thereby orienting the complex with respect to lumenal/extracellular, cytosolic and transmembrane region. The transmembrane region appears as a high-density belt but with low-density regions that make be sites of entry for catalytic water and a surface groove that may be the substrate docking site. The most recent 4.5 Å cryo-EM structure (Lu *et al.*, 2014), solved using a combination of improved expression and purification and the more sensitive direct electron detector system. The TMDs of the complex were arranged in a horseshoe shape, with the part of the nicastrin ectodomain implicated in substrate recognition intriguingly located above the horseshoe cavity (Figure 2). Thus, nicastrin appears to be in position to guide the substrate into the horseshoe and the TMD active site of the complex. The location of presenilin within the arrangement of TMDs is unclear, despite the prior elucidation of a higher-resolution structure of an archaeal presenilin homolog.

Figure 2 Architecture of the γ -secretase complex and implications for substrate access and recognition. Top: A recently reported 4.5 Å cryo-EM structure reveals a horseshoe-shaped arrangement of TMDs and a bi-lobed nicastrin ectodomain. The nicastrin sequence and structure is homologous to a peptidase, but without catalytic activity of its own. Nicastrin's catalytically dead site (red star) is part of a groove located above the opening to the horseshoe-shaped TMD arrangement and may be important for substrate recognition. Bottom: Speculated arrangement of specific TMDs of PS1 (numbered) and Pen-2 (P) in the thick end, based in part on the structure of an archaeal presenilin homolog. TMDs of Aph-1 and nicastrin are nonspecifically assigned to the thin end. Substrate (S) approaches the active site of PS1 via the cavity.

Prospects for Therapeutics

While many γ -secretase inhibitors and modulators have been reported, only a handful of these have entered into clinical trials (Crump *et al.*, 2013). The first modulator into the clinic was R-flurbiprofen (Eriksen *et al.*, 2003; Kukar *et al.*, 2007; Wilcock *et al.*, 2008), the enantiomer of the nonsteroidal anti-inflammatory drug (NSAID) S-flurbiprofen. A number of NSAIDs show A β 42-lowering effects on γ -secretase processing of APP (these were the first γ -secretase modulators discovered (Weggen *et al.*, 2001)), but this activity does not correlate with inhibition of the NSAID target cyclooxygenase. Indeed, R-flurbiprofen is not a cyclooxygenase inhibitor, and A β 42-lowering NSAIDs do so even in cyclooxygenase-deficient cells. However, R-flurbiprofen is a very weak modulator, and despite being quite safe, even very high doses were not efficacious in patients (Green *et al.*, 2009). Other, much more potent second- and third-generation modulators have since been developed (Crump *et al.*, 2013), but so far none have reached late-stage clinical trials.

A major problem with clinical trials for γ -secretase modulators, as with all candidate AD therapeutics to date, has been that patients enrolled to test these agents already had mild-to-moderate AD. As substantial neurodegeneration of the hippocampus – a brain region critical to learning and memory – has occurred by the time AD manifests itself cognitively (Barnes *et al.*, 2009), reducing A β 42 levels at this point is unlikely to be effective. Thus, there is intense interest in AD biomarkers and diagnostics, in order to identify presymptomatic subjects who are highly likely to develop AD within the span of a clinical trial (Sperling *et al.*, 2011). Presymptomatic carriers of FAD mutations are of particular interest for new drug trials.

γ -Secretase inhibitors, however, have other, much more serious problems. As mentioned earlier, γ -secretase cleavage of Notch receptors is an essential part of a signaling pathway critical for many different cell-fate determinations, both in embryogenesis and in adulthood (Kopan and Ilagan, 2009). γ -Secretase inhibitors cause a variety of toxic effects, all related to deficient Notch signaling, including immunosuppression, gastrointestinal bleeding and diarrhea, and cancerous skin lesions. For these reasons, a potent, brain-penetrant γ -secretase inhibitor (semagacestat) was halted in late-phase clinical trials (Doody *et al.*, 2013). Even more worrisome, this compound caused cognitive worsening in AD patients. While this disturbing result may be linked to inhibition of Notch signaling, it is also possible that elevation of APP CTFs is responsible, as cognitive worsening with γ -secretase inhibitors has been seen at lower doses in APP transgenic mice than in wild-type mice (Mitani *et al.*, 2012). Indeed, another clinical candidate (ava-gacestat), with selectivity for inhibiting γ -secretase cleavage of APP over that of Notch (Gillman *et al.*, 2010), also caused cognitive worsening and was halted after phase II trials (Coric *et al.*, 2012). Discerning whether elevated APP CTFs is responsible for cognitive worsening is critically important in deciding whether further development of γ -secretase inhibitors that avoid effects on Notch function is a sensible approach. If instead cognitive worsening is due to blocking Notch signaling, improving on APP/Notch selectivity would be potentially worthwhile, as would targeting specific isoforms of the γ -secretase complex.

The Calpain Proteolytic System

Y Luo, National Institute of Infectious Diseases, Tokyo, Japan

Introduction

Calpains are a distinct group of ubiquitously expressed eukaryotic cysteine proteases dependent upon Ca^{2+} and a neutral pH for their enzymatic activity. Unlike many other cysteine proteases, they are located in the cytoplasm rather than in membrane-limited compartments such as lysosomes, allowing their enzymatic products to participate in various cellular processes (Sorimachi *et al.*, 2011). Together with calpastatin, the only known endogenous inhibitor of calpain, this family of structurally similar proteases constitutes the 'calpain proteolytic system.'

The calpain proteolytic system is distinct from other intracellular proteolytic systems, such as the ubiquitin-proteasome system (Tanaka, 2009), the autophagy-lysosome system (Mizushima and Levine, 2010), and caspases (Tait and Green, 2010). The ubiquitin/proteasome and autophagy/lysosome systems recognize their substrates only after those substrates are tagged, either by ubiquitinylation, or incorporation into membrane-delimited autophagosomes, respectively. These two systems essentially operate as 'scavengers' to degrade and eliminate unneeded and damaged proteins from the cell. Caspases, on the other hand, are activated by sequence-specific substrate recognition signals, and rather than engaging directly in the elimination of worn proteins, they play important roles in cascades leading ultimately to apoptosis. Moreover, in contrast to caspases, the calpains recognize the tertiary structure of protein substrates rather than specific amino acid sequences.

The most important distinction between the calpains and other proteolytic systems is that whereas the others function in the degradation or elimination of intracellular proteins, calpain proteolysis acts to modify the structures and activities of their substrates, rather than destroying them. The altered calpain substrates are then available for participation in intracellular signaling. Thus this unique enzyme system has acquired the designation as an intracellular 'modulator' protease system (Ono *et al.*, 2004).

To date, the scope of revealed calpain action in cells includes basic processes like cell cycle progression, apoptosis, cell adhesion, and cell mobility, in addition to a number of cell-type specific functions. Furthermore, several specific pathologies have been linked to mutations and dysfunction of specific calpain subtypes, suggesting that novel treatments for these diseases may in the future employ the inactivation of the calpain proteolytic system with specific calpain inhibitors.

Structure of Conventional Calpains

The most extensively studied calpains are the two major ubiquitous mammalian calpains: calpain 1 and calpain 2, often

referred to as the 'conventional' calpains. All other calpains are referred to as 'unconventional' calpains, and their structure is compared to that of the conventional calpains as the standard reference for further classification into 'classical' and 'non-classical' forms (Figure 1).

The conventional calpains, μ - and m-calpain, are heterodimers consisting of a large catalytic subunit (CAPN1/ μ CL and CAPN2/mCL, for μ - and m-calpain, respectively) and a common small regulatory subunit (CAPNS1/30K) unique to the conventional calpains (Figure 1). Calpain 1 and calpain 2 are the heterodimers of CAPN1/ μ CL or CAPN2/mCL and CAPNS1/30K, respectively. The large subunits CAPN1/ μ CL and CAPN2/mCL possess approximately 60% amino acid identity, and therefore have almost indistinguishable substrate and inhibitor specificities. However, as reflected in their designations as μ CL ('micromolar' CL) and mCL ('millimolar' CL) respectively, these subunits differ greatly in their requirement for Ca^{2+} . Thus, μ CL activation requires Ca^{2+} in the micromolar range, whereas mCL requires Ca^{2+} at 1000-fold greater concentration. The functions of calpains 1 and 2 are fundamental and essential to the cell, and have been implicated in numerous biological processes, including the regulation of signal transduction (Pontremoli and Melloni, 1988; Noguchi *et al.*, 1997), cell motility (Leloup *et al.*, 2010; Wells *et al.*, 2005); membrane repair (Mellgren and Huang, 2007; Mellgren *et al.*, 2007), and apoptosis (Danial and Korsmeyer, 2004; Nakagawa and Yuan, 2000), although their precise roles in these events remain elusive.

The catalytic and regulatory subunits of the conventional calpains are each divided into several domains (Figure 1). The catalytic subunit is comprised of four distinct domains: an N-terminal anchor helix, a CysPc protease domain, a C2 domain-like (C2L) region and a penta-EF-hand large (PEF(L)) domain. The regulatory subunit CAPNS1 consists of two domains: an N-terminal Gly-rich (GR) domain and a penta-EF-hand small (PEF(S)) domain (Figure 1). The two PEF domains, PEF(L) and PEF(S), each have five EF-hand motifs, and the fifth motif in each contributes to the heterodimerization of the catalytic and regulatory subunits (Imajoh *et al.*, 1987).

The N-terminal anchor helix in the catalytic subunit interacts with the second EF-hand motif (EF-2) of the PEF(S) domain of the regulatory subunit CAPNS1. Upon activation of the calpain complex, the interaction of the catalytic and regulatory units is disrupted by either autolysis of N-terminal anchor helix or by binding of Ca^{2+} to the EF-2 motif. Autolysis of N-terminal anchor helix upon activation by Ca^{2+} enables the enzyme to function at a lower Ca^{2+} concentration (Cong *et al.*, 1989; Hathaway *et al.*, 1982; Inomata *et al.*, 1988; Suzuki *et al.*, 1981), and with different substrate specificity from before. Therefore, autolysis of the N-terminal anchor helix domain is considered to be an important regulatory mechanism for the activity of conventional calpains.

Figure 1 Schematic structures of human calpains. The two major ubiquitous human calpains: calpain 1 and calpain 2, are often referred to as the conventional calpains, while all others are referred to as the unconventional calpains. Human calpains are classified into classic and non-classic types according to their structural similarity compared to the conventional calpains, calpain 1 and calpain 2 (Sorimachi *et al.*, 2011). The structure of conventional calpains consists of two subunits: the catalytic and regulatory subunits. The catalytic subunit consists of four distinct domains: an *N*-terminal anchor helix, a CysPc protease domain, a C2 domain-like (C2L) domain and a penta-EF-hand (PEF) large domain. The regulatory subunit CAPNS1 consists of two domains: an *N*-terminal Gly-rich domain and a PEF small domain. Non-classical calpains lack C2L and PEF domains and instead often have characteristic functional domain(s) of their own. The structural domains are indicated by their abbreviation: PC1 (protease core domain1), PC2 (protease core domain2), C2L (C2 domain-like), PEF(L) (penta-EF-hand large domain), PEF(S) (penta-EF-hand small domain), GR (*N*-terminal Gly-rich domain), NS/IS1/IS2 (three unique insertions in calpain 3), C2 (C2 domain), MIT (microtubule interacting and transport motif), Zn (Zn finger containing domain), SOH (SOL homology domain), IQ (calmodulin interacting motif).

Classification of Calpains

Since the conventional calpain catalytic subunits (CAPN1/ μ CL and CAPN2/mCL) in the human serve as the reference for describing the structure of other calpains, calpains with a domain structure similar to the conventional calpains are called ‘classical’ calpains. In these calpains, the CysPc protease domain of the catalytic unit is followed by the C2L and PEF domains. In contrast, non-classical calpains lack the C2L and/or the PEF domains (Sorimachi *et al.*, 1993; Figure 1). Instead, they may possess functional domain(s) of their own. The structural domains are indicated by their abbreviation: PC1 (protease core domain1), PC2 (protease core domain2), C2L (C2 domain-like), PEF(L) (penta-EF-hand large domain), PEF(S) (penta-EF-hand small domain), GR (*N*-terminal Gly-rich domain), NS/IS1/IS2 (three unique insertions in calpain 3), C2 (C2 domain), MIT (microtubule interacting and transport motif), Zn (Zn finger containing domain), SOH (SOL homology domain), IQ (calmodulin interacting motif) (Figure 1). The nine human classical calpains are calpains 1, 2, 3, 8, 9, 11, 12, 13, and 14 (Macqueen *et al.*, 2010; Figure 1). Although they share strong similarities in amino acid sequence, their function and tissue distribution can differ greatly from each other (Table 1).

The expression of six human calpain genes, including CAPN3, 6, 8, 9, 11, and 12, are tissue-specific, while the others, including those encoding the conventional calpains, are expressed ubiquitously (Table 1). In the human, CAPN3 is expressed in skeletal muscle (Sorimachi *et al.*, 1993), CAPN6 in the placenta and embryonic muscles (Dear *et al.*, 1997), CAPN8 and CAPN9 in the gastrointestinal tract (Sorimachi *et al.*, 1993), CAPN11 in the testis (Sorimachi

et al., 1993), and CAPN12 in hair follicles (Dear *et al.*, 2000), each having a specific intracellular function or functions reflecting its tissue-specific expression. In contrast, the ubiquitous calpains are thought to play fundamental roles in the cell. The classification of calpains as having primarily ‘tissue-specific’ or ‘fundamental’ activities has been supported by the observation of several kinds of calpain gene knockout mouse models. Defects seen in *Capn2*^{-/-} and calpain small subunit *Capns1*^{-/-} mice can be embryonic lethal (Arthur *et al.*, 2000; Dutt *et al.*, 2006; Shimada *et al.*, 2008; Takano *et al.*, 2011), whereas defects in tissue-specific calpains usually cause tissue-specific phenotypes. The roles of calpains in different systems *in vivo* will be further reviewed in the following articles.

Regulation and Activation of Calpains

The Smaller Regulatory Subunit, CAPNS1/30K

CAPNS1/30 K is an important and unique regulatory subunit for conventional calpains. It has been reported that CAPNS1/30 K is indispensable for the stability and activation of conventional calpains. In *Capns1*^{-/-} mice, the expression of both subunits of CAPN1/ μ CL and CAPN2/mCL are almost completely down-regulated resulting in embryonic lethality of almost all mice before E11.5 (Arthur *et al.*, 2000; Zimmerman *et al.*, 2000). Regarding the role of the regulatory unit in

Table 1 The expression distribution and classification of human calpains

<i>Protein</i>	<i>Gene</i>	<i>Tissue distribution</i>	<i>Classification</i>	<i>Physiological function</i>	<i>Pathological involvement</i>
μ -Calpain large subunit	<i>CAPN1</i>	Ubiquitous	Classical	Normal central nervous system functions, normal cardiovascular functions ^a	Central nervous system diseases, cardiovascular diseases ^a

^aAlso involved in variety of physiological functions and human diseases, as conventional calpains are fundamental regulators of many physiological and pathological functions.

activation of calpains, it has been shown that it is very difficult to activate CAPN2/mCL in the absence of CAPNS1/30K *in vitro* (Yoshizawa *et al.*, 1995). So far, CAPNS1/30K has only been shown to be necessary for activation of conventional calpains.

Ca²⁺: The Main Calpain Activator

Since the activation of conventional calpains is Ca²⁺-dependent, numerous studies have been aimed at identifying the location of the Ca²⁺-binding site responsible for calpain activation. 3D structure analysis has revealed that the active protease domain is formed by the fusion of core domain PC1 and PC2 upon the binding of one Ca²⁺ to each of the core domains. Thus, the activation of the conventional calpains entails the binding of Ca²⁺ to the protease domain itself (Moldoveanu *et al.*, 2002; Moldoveanu *et al.*, 2003).

As mentioned above, the activation of conventional calpains requires a high Ca²⁺ concentration (in the range of 10 mM or greater) that is seldom available *in vivo*, so the

means by which the conventional calpains are activated in the presence of low physiologic Ca²⁺ concentrations is another topic of intense study. One proposed mechanism suggests that specific intracellular molecules such as membrane phospholipids could lower the required Ca²⁺ concentration for calpain activation (Tomba *et al.*, 2001; Shao *et al.*, 2006). Another possibility is that a very small number of calpain molecules localized in a small region with a high local Ca²⁺ concentration are sufficient to excise calpain function. The neuromuscular junction (NMJ) where Ca²⁺ and Na⁺ undergo rapid, massive and localized changes in concentration is believed to be one such region favorable for calpain activation. In fact, the abnormal activation of calpains in the post-synaptic muscle fiber of the NMJ is believed to be one of the mechanisms underlying the development of slow-channel myasthenic syndrome, an inherited neuromuscular disorder (Groshong *et al.*, 2007). In this disease, Ca²⁺ overload occurs at the NMJ due to mutations in the genes encoding nicotinic acetylcholine receptor in the post-synaptic (muscle cell) membrane. The elevated Ca²⁺ at the synapse, in turn, could

result in the abnormal activation of Ca^{2+} -dependent processes including calpain activation. This hypothesis is supported by studies showing that the transgenic overexpression of calpastatin ameliorates the symptoms of slow-channel myasthenic syndrome in a mouse model of this disease.

Calpastatin: The Endogenous Calpain Inhibitor

Calpastatin is the only known endogenous inhibitor of calpains (Kiss *et al.*, 2008). Although calpastatin inhibits mainly the conventional calpains, it has been reported that calpastatin also suppresses the activity of several unconventional calpains *in vitro*, including calpain 8 (Hata *et al.*, 2007) and calpain 9 (Lee *et al.*, 1999). Furthermore, although calpastatin does not affect calpain 3 activity *per se*, calpain 3 can inactivate calpastatin through partial proteolysis, permitting a regulatory effect of calpain 3 on calpastatin and conventional calpains in skeletal muscle (Ono *et al.*, 2004).

The calpastatin molecule is divided into four inhibitor units, each of which inhibits one calpain molecule with variable efficiency (Emori *et al.*, 1987; Maki *et al.*, 1987a; Maki *et al.*, 1987b). Oligopeptides as short as 20 amino acids derived from these inhibitory units can also inhibit calpain, although with reduced efficacy compared with the whole molecule. 3D structure analysis of the co-crystallization of calpastatin and CAPN2/mCL with Ca^{2+} has revealed one of the mechanisms underlying the inhibitory effect of calpastatin on conventional calpains. When calpastatin interacts with CAPN2/mCL in the presence of Ca^{2+} , calpastatin develops a kink between its flanking residues, L173/L612 on one side of the catalytic cleft between PC1 and PC2 in CAPN2/mCL, and T179/T618 at the other side. This kink allows several adjacent amino acid residues in calpastatin to loop out from the proteolytic active site on CAPN2/mCL (Hanna *et al.*, 2008; Moldoveanu *et al.*, 2008), permitting calpastatin to bind CAPN2/mCL tightly without being proteolyzed. Calpastatin mutagenesis studies have confirmed the importance of this 'kink' in the inhibitory effect of calpastatin.

Unique Regulation of Unconventional Calpains

As described above, conventional mammalian calpains exhibit the following basic features: (1) CAPN1/30K forms heterodimers with CAPN1/ μ CL or CAPN2/mCL to maintain calpain stability and activity, (2) calpastatin exerts inhibitory effects on proteolysis by calpain, and (3) Ca^{2+} binds to the protease domain to initiate enzymatic activity. The non-conventional calpains, however, possess some unique regulatory mechanisms not seen in the conventional calpains.

Calpain 3, which is specifically expressed in skeletal muscle in the human, is approximately 50% identical to CAPN1/ μ CL and CAPN2/mCL (Figure 1). Two NS insertions, located at the N-terminus of the PC2 domain, and between C2L and the PEF domains (termed IS1 and IS2, respectively), confer a unique *in vitro* susceptibility of calpain 3 to a rapid (<10 min duration) autodegradation that distinguishes it from all other members of the calpain family (Zimmerman *et al.*, 2000; Ono *et al.*, 2007; Ono *et al.*, 2006). Calpain 3 variants missing either IS1 or IS2 degrade much slowly, indicating that the two

insertions are essential for the rapid degradation of substrates (Sorimachi *et al.*, 1993). Moreover, autodegradation has been shown to occur Na^{+} -dependently and in the absence of Ca^{2+} , thus making calpain 3 the first example of an intracellular Na^{+} -dependent enzyme (Ono *et al.*, 2010). In addition, the substrates of Na^{+} -activated calpain 3 differ from those of the Ca^{2+} -activated enzyme (Ono *et al.*, 2010).

Calpain 8 and calpain 9 are specifically expressed in the gastrointestinal tract and form the heterodimer calpain 8/calpain 9 (G-calpain) *in vivo* (Hata *et al.*, 2010). The formation of this heterodimers has been shown to be essential for the stability of these two calpains. Other calpain subtypes are undoubtedly regulated by as yet undefined mechanisms that are specific to the precise structure and function of each.

Calpains in Apoptosis

Studies showing the involvement of calpains activation in apoptosis are abundant and still growing in number. However, the role of calpains in apoptosis is very complex, and ordinarily dependent on the specific cellular context. Thus, both pro- and anti-apoptotic functions of calpains have been observed, and those functions are now considered to be associated with the pathogenesis of various human diseases. In the following sections, we will summarize various pathways linking calpain activation and apoptosis, as a prelude to describing the role of the calpain proteolytic system in specific human diseases.

Relationship between Calpain and Caspases

Caspases, best known for their essential roles in apoptosis, interact with the calpain proteolytic system in several important ways. Not only have calpains and caspases been shown to exert their enzymatic activity on many of the same substrates (Nakagawa and Yuan, 2000), but they have also been reported to serve as substrates for each other (Waterhouse *et al.*, 1998; Chua *et al.*, 2000).

Furthermore, although calpains usually activate caspases indirectly, through the cleavage and degradation of endogenous caspase inhibitors (Mikosik *et al.*, 2007; Porn-Ares *et al.*, 1998; Wang *et al.*, 1998), the direct regulation of caspases by calpains is also possible (Wood and Newcomb, 1999). As an example, it was demonstrated that activation of calpains resulted in caspase 3 activation and subsequent apoptosis in cells undergoing radiation-induced death (Waterhouse *et al.*, 1998). It was also reported that calpains can activate caspase 7 directly through cleavage at specific sites, both *in vivo* and *in vitro* (Ruiz-Vela *et al.*, 1999), and that they can also activate caspase 12 to initiate stress- and ischemic injury-induced apoptosis (Tan *et al.*, 2006). On the other hand, a study of drug-induced apoptosis in human neuroblastoma cell lines showed that calpains indirectly induce the cleavage of pro-caspase, resulting in permanent caspase inactivation (McGinnis *et al.*, 1999). Moreover, several calpains have been shown to inactivate caspases 7, 8, and 9 via proteolysis at specific cleavage sites in the caspase molecules, and conversely, calpains have been shown to possess a set of specific cleavage sites for caspase activity

(Chua *et al.*, 2000). Thus, the complex, reciprocal relationship between calpains and caspases can result in either pro- or anti-apoptotic effects of the calpains, depending on precisely which cell context, calpain subtypes, caspase subtypes, and enzymatic substrates are involved (Chua *et al.*, 2000; Waterhouse *et al.*, 1998; McCollum *et al.*, 2002).

Other Molecules Involved in Calpain-Mediated Apoptosis

Calpains also mediate apoptosis through their interactions with members of the B cell lymphoma 2 (Bcl 2) protein family, another important regulator of apoptosis whose members regulate apoptosis via changes in outer mitochondrial membrane permeability. Specifically, calpains are known to cleave and activate the Bcl-2 associated X (Bax) protein which is then able to permeabilize the mitochondrion and initiate a cytochrome *c*/caspase cascade leading to cell death (Cao *et al.*, 2003). On the other hand, the Bax fragments produced by calpain cleavage are thought to lose their ability to interact with and block the action of the anti-apoptotic proteins Bcl-2 and Bcl-xL. Thus, the cleavage of Bax by calpains could have both pro- and anti-apoptotic effects whose balance can shift with changes in the intracellular milieu. Moreover, it has been shown that calpain inhibitors can block or at least attenuate Bax-mediated apoptosis in chemotherapy drug-treated cells, suggesting that calpain dysregulation could play a role in the acquisition of chemotherapy resistance. As an example of this, an *in vitro* study has shown that pretreatment of human leukemic cell lines with calpeptin (a calpain inhibitor) blocks the ability of etoposide (a widely used chemotherapy drug) to induce Bax cleavage and subsequent apoptosis (Gao and Dou, 2000). Another substrate of calpain responsible for the initiation of an apoptotic cascade is the BH3 interacting-domain death agonist (Bid) protein, which is known to cause Bax insertion into the outer mitochondrial membrane (Mandic *et al.*, 2002). The cleavage of Bid by calpain leads to mitochondrial permeabilization and apoptosis during myocardial ischemia reperfusion (Mandic *et al.*, 2002).

Drug-Induced Apoptosis and Calpain

Chemotherapy-induced apoptosis has been reported in many studies to involve the activation of conventional calpains. For example, it was reported that activation of calpain 1 contributes to the genistein-induced apoptosis of MCF-7 breast cancer cells (Sergeev, 2004). This process could conceivably occur via the genistein-induced release of Ca^{2+} from the endoplasmic reticulum into the cytoplasm, where it would then bind to and activate calpain to modify its substrate, caspase 7, and initiate an apoptotic cascade (Shim *et al.*, 2007). Similarly, calpain 2 has been shown to be associated with genistein-induced apoptosis in hepatocellular carcinomas via activation of caspase 12 (Yeh *et al.*, 2007). Conventional calpains are also reported to mediate the induction of apoptosis by the widely used chemotherapy drugs cisplatin and oxaliplatin in human lung adenocarcinoma and cervical carcinoma cells, respectively (Liu *et al.*, 2008; Anguissola *et al.*, 2009) and by aspirin and curcumin, respectively, in cervical carcinoma and glioblastoma cells (Lee *et al.*, 2008; Karmakar *et al.*, 2007). The broad range

of anti-tumor drugs dependent on calpain activation, and the large number of tumor types affected suggest that calpains could represent a very promising target for future chemotherapies. On the other hand, a recent study has shown the deregulation of conventional calpains may be involved in the acquisition of chemotherapy resistance. In the report, the sensitivity of breast cancer cells to trastuzumab was reduced by the deregulation of calpain activation, suggesting that trastuzumab resistance in chemotherapy of human breast cancer could be overcome by targeting calpain activity (Kulkarni *et al.*, 2010). The studies described above highlight a potentially very important role of calpains in both chemotherapy of a wide range of tumors, and in overcoming the drug-resistance that often occurs during chemotherapy.

Physiological Functions of Calpains and the Role of Dysregulation in Human Disease

Calpain dysregulation is believed to enzymatically alter many additional intracellular proteins resulting in either excessive protein degradation or accumulation, or changes in function that ultimately lead to the development of a variety of human diseases. In this section, we present an overview of the molecular evidence linking calpain dysregulation to the etiology of those diseases.

Central Nervous System

Conventional calpains are ubiquitously expressed in the brain and contribute to its normal functions (Goll *et al.*, 2003) (Table 1). However, persistent activation of calpains induced by the disruption of calcium homeostasis could result in abnormal elevation in the cleavage of neuronal substrates to cause changes in neuronal structure and function. To date, the sustained activation of calpains has been reported in both acute neuronal damage resulting from trauma (Kampfl *et al.*, 1996) and in several chronic neurodegenerative diseases including Alzheimer's disease, Parkinson's disease and Huntington's disease (Vosler *et al.*, 2008) (Table 1). As a result of these findings, calpain inhibitors have been extensively studied as potential therapeutic agents in the treatment of central nervous system (CNS) diseases.

Calpain activation after experimental traumatic brain injury (TBI) was first reported in a rat model of percussion brain injury, using a combination of immunoblotting and immunohistochemical techniques to detect specific breakdown products of α II-spectrin (Saatman *et al.*, 1996a), a cytoskeletal protein that under normal circumstances provides structural support to the plasma membrane of axons and pre-synaptic terminals. Increased cleavage of α II-spectrin by calpain acts to destabilize additional proteins in the neuron cell membrane, thus making axons more vulnerable to traumatic injury. By assessing α II-spectrin proteolysis as a marker of calpain activation, TBI development has been confirmed to occur as a consequence of calpain activity in commonly used rat, mouse (Saatman *et al.*, 2003) and several other types of *in vivo* TBI models (Hall *et al.*, 2005; Kupina *et al.*, 2001), suggesting that posttraumatic calpain activation may be a key event in the subsequent development of both focal and diffuse brain

injury. Moreover, the specific inhibition of calpain activation in a rat model of brain trauma has been reported to attenuate of α II-spectrin proteolysis (Posmantur *et al.*, 1997; Saatman *et al.*, 1996b), neuronal damage, and behavioral deficits (Saatman *et al.*, 1996b), suggesting the application of calpain inhibitors as a potential therapeutic approach in the treatment of TBI.

Abnormal calpain activation has also been reported as a factor underlying the development of brain damage induced by cerebral ischemia. The mechanism is thought to involve the post-ischemic over-activation of cerebral glutamate receptors, causing a sharp increase of intracellular Ca^{2+} that could reach the threshold for calpain activation. Thus activated calpains could further increase the intracellular Ca^{2+} concentrations through the cleavage of several calcium-handling substrates, such as calcium regulatory proteins in the cell membrane (L-type calcium channels (De Jongh *et al.*, 1994; Hell *et al.*, 1996), plasma membrane calcium ATPase (PMCA) (Pottorf *et al.*, 2006), and the sodium–calcium exchanger (NCX) (Bano *et al.*, 2005)). Additionally, calpain may alter cell survival signals to increase the vulnerability of neuronal cells to apoptosis. One such pro-apoptotic mechanism is the calpain-induced uncoupling of the N-methyl-D-aspartic acid receptor (NMDAR) from cell survival-promoting signal cascades (including the phosphatidylinositol 3 kinases/protein kinase B and protein kinase A pathways), and the subsequent initiation of mitochondrial dysfunction (Gascon *et al.*, 2008). Other mechanisms resulting in neural damage include the modulation of neuronal transcription by calpains through their direct cleavage of specific transcription factors (Sp3 and Sp4) (Mao *et al.*, 2007), or through their interactions with calcineurin (Wu *et al.*, 2007), cyclin-dependent kinase (Rashidian *et al.*, 2005), and collapsin response mediator protein-3 (Hou *et al.*, 2006).

One of the most important areas of research into abnormal calpain activation in human disease is the role of calpains in Alzheimer's disease. Alzheimer's disease is characterized by pathological deposits of amyloid β -protein ($\text{A}\beta$) in senile plaques (Haass and Selkoe, 2007), intracellular neurofibrillary tangles (NFTs) comprised of hyperphosphorylated aggregates of tau protein (Grundke-Iqbal *et al.*, 1986), synaptic dysfunction and neuronal death. Although the pathological mechanisms underlying Alzheimer's disease have not yet been fully explained, convincing evidence shows that disrupted neuronal calcium homeostasis is a key factor. Elevated concentrations of soluble $\text{A}\beta$ produced by the integral membrane protein amyloid precursor protein (APP) are thought to lead to NMDAR activation and an increase of intracellular calcium (De Felice *et al.*, 2007; Demuro *et al.*, 2005). Evidence of increased calpain activation by calcium has been confirmed in the post mortem examination of brains from patients with Alzheimer's disease (Nixon *et al.*, 1994; Saito *et al.*, 1993). Moreover, a recent study suggests that the pathological activation of calpain can induce the cleavage of sodium–calcium exchanger 3 (NCX3) in the patient's brain. Reduced calcium transporter activity of the cleaved NCX3 substrate would be expected to cause the sustained increases of intracellular calcium level that are required to initiate the synaptic and neuronal dysfunction characteristic of the disease (Chen and Fernandez, 2004).

Despite the increasingly clear role of calpains in Alzheimer's disease etiology, treatments for Alzheimer's disease aimed at inhibiting calpains may actually induce some of the suspected causative conditions for this disease. For example, calpain has been proposed as a candidate α -secretase responsible for the normal regulation of APP (Li *et al.*, 1995; Chen and Fernandez, 2005). Likely as a consequence of this function, the inhibition of calpain 1 activity using specific siRNA was seen to decrease overall APP release, but actually increased $\text{A}\beta$ production (Atherton *et al.*, 2013). Effective Alzheimer's therapies would therefore need to preserve the beneficial actions of calpain inhibition, while attempting to limit the potentially damaging effects of elevated $\text{A}\beta$ production that results from it.

Hyperphosphorylation and subsequent aggregation of tau protein is yet another calpain-dependent molecular mechanism contributing to the progression Alzheimer's disease. Calpain is thought to contribute to the hyperphosphorylation of tau through the regulation of kinase substrates, one of which has been identified as mitogen-activated protein kinase Erk 1/2 (Veeranna *et al.*, 2004). An *in vitro* study showed that treatment of primary cultures of neurons with the calcium ionophore ionomycin caused tau hyperphosphorylation via the activation of calpain and the subsequent activation of Erk 1/2. Calpain may also increase kinase activity (Kishimoto *et al.*, 1989) and tau hyperphosphorylation (Lucas *et al.*, 2001) through cleavage of protein kinase C (PKC) and calcium/calmodulin kinase (CamK) II, and by removing the inhibitory domain (GSK-3 β) from glycogen synthase kinase 3 (GSK-3) (Lucas *et al.*, 2001; Goni-Oliver *et al.*, 2007). Active GSK-3 in addition to hyperphosphorylation of tau may contribute to Alzheimer's disease via inducing neuronal death through the β -catenin pathway (Lucas *et al.*, 2001).

$\text{A}\beta$, in addition to increasing calpain activity via Ca^{2+} elevation, has been shown to contribute to the calpain-induced hyperphosphorylation and cleavage of tau into a toxic 17 kDa fragment (Park and Ferreira, 2005) that promotes cell death in neurons. Neuronal damage caused by this fragment is not unique to Alzheimer's disease (Amadoro *et al.*, 2006). The mechanism underlying the toxicity of tau fragments is thought to involve fragment translocation into the nucleus, but the details of the process remain largely unknown.

Calpains have also been identified as playing important pathologic roles in the neurodegenerative diseases of external CNS sensory receptors such as the eye. One such disease is glaucoma, a disease wherein conventional calpains participate in the progressive retinal degeneration that eventually results in vision impairment and blindness. The process is thought to occur as the increased intraocular pressure due to blocked outflow of aqueous humor triggers calcium dyshomeostasis in retinal ganglion cells, which in turn activates calpain to cleave caspase and initiate an apoptotic cascade. It is the progressive loss of retinal ganglion cells in this disease that leads to blindness (Huang *et al.*, 2010). Another mechanism through which calpain dysregulation contributes to glaucoma involves the overexpression of calpain rather than its hyperactivation. The hypothesized mechanism for the elevated calpain levels is the impairment of calpain degradation due to the accumulation of lipid oxidation products, such as iso[4]levuglandin E2, in the cell. As in several other neurodegenerative diseases

in which calpain dysfunction is the suspected cause, the systemic delivery of calpain inhibitors in patients at risk for glaucoma has been proposed as a protective strategy (Govindarajan *et al.*, 2008).

Cardiovascular System

The dysregulation of conventional calpains has been linked to a wide range of cardiovascular disorders (Shao *et al.*, 2006; Iwamoto *et al.*, 1999; Li *et al.*, 2011; Mani *et al.*, 2008; Singh *et al.*, 2004; Sorimachi and Ono, 2012; Table 1), including coronary contractile dysfunction, cardiac ischemia/infarction, hypertension, atherosclerosis, myocardial stunning, and diabetes-associated cardiovascular disease. It has also been reported that many of these conditions are improved or ameliorated by inhibition of calpain activity, suggesting that over-activation of calpains might have a role in causing these diseases.

Mice receiving chronic infusions of angiotensin II or genetically lacking low-density lipoprotein receptor (*Ldlr*) are useful animal models for studying the development and treatment of such cardiovascular disorders as hypertension and atherosclerosis. Transgenic overexpression of calpastatin in chronically angiotensin II-infused mice was found to suppress hypertrophy of the left ventricle and tunica media, and the perivascular inflammation and fibrosis induced by the elevated levels of angiotensin II (Letavernier *et al.*, 2008). Similarly, the endogenous calpain inhibitor was found to ameliorate the atherosclerosis and abdominal aortic aneurysms induced by angiotensin-II infusion in *Ldlr*^{-/-} mice (Subramanian *et al.*, 2012).

Vascular endothelial cadherin (VE-cadherin) is a recognized substrate for calpain 2 expressed in coronary arteries. Miyazaki *et al.* (Miyazaki *et al.*, 2011) have reported that both calpain 2 levels and VE-cadherin proteolysis are increased in aortic endothelial cells from atherosclerotic lesions in human patients and from the *Ldlr*^{-/-} mouse model of atherosclerosis. Treatment with either specific siRNA against *CAPN2*, or with calpain inhibitors was seen to attenuate this condition, suggesting that increased calpain 2-induced VE-cadherin proteolysis represents a potential mechanism underlying the development of atherosclerosis.

Myocardial stunning (also called broken-heart syndrome or transient left ventricular apical ballooning), a form of cardiac dysfunction caused by post-ischemic reperfusion, is another cardiovascular disorder whose etiology involves the over-activation of calpain (Bolli and Marban, 1999). Specifically, myocardial stunning is suspected to be due to the increased proteolysis of the cardiac troponin I subunit (cTnI) by calpain (van der Laarse, 2002; Maekawa *et al.*, 2003). However, relevant studies are still controversial (Colantonio *et al.*, 2004; Galvez *et al.*, 2007; Thomas *et al.*, 1999).

It has also been reported that diabetes-associated cardiovascular complications in animal models are improved by the disruption of conventional calpains. In one investigation, the knockdown of either *Capn1* or both *Capn1* and *Capn2* together was seen to mitigate the myocardial hypertrophy and fibrosis in the mouse model of type 1 diabetes (Li *et al.*, 2011). In other studies, the inhibition of calpain activity mitigated

hyperglycemia in animal models of both type 1 (Smolock *et al.*, 2011) and 2 diabetes (Scalia *et al.*, 2007).

In addition, it has been proposed that calpain-induced over-activation of protein kinase C (PKC) may be a contributory factor in the development of some forms of cardiomyopathy (Kang *et al.*, 2010; Zhang *et al.*, 2011). Normally, PKC is maintained in an inactive state by the presence of a regulatory domain within the N-terminus of the molecule. However, intracellular events leading to PKC proteolysis by the conventional calpains could cut off that regulatory domain to produce a proteolytic fragment of PKC called PKM that remains constitutively active regardless of upstream regulatory signals (Kishimoto *et al.*, 1983). Constant activation of PKM, in turn, would then induce hyperphosphorylation of various substrates, including myosin-binding protein C and histone deacetylase 5 (HDAC5), resulting in morbid cellular responses, such as a constitutive export of HDAC5 from the nucleus that leads to cardiomyopathy.

Calpains in Skeletal Muscle

CAPN3 mutations were shown to be responsible for limb-girdle muscular dystrophy type 2A (LGMD2A) (also called calpainopathy) (Table 1) using a genotypic analysis of families residing in the French-owned island of Réunion and through positional cloning (Richard *et al.*, 1995; Chiannikulchai *et al.*, 1995). The involvement of calpain 3 defects in this disease received additional support from experimental studies showing that *Capn3*^{-/-} mice display a phenotype similar to human LGMD2A (Richard *et al.*, 2000). *Capn3* knock-in (*Capn3*^{CS/CS}) mice, which express a structurally intact calpain 3 mutant lacking proteolytic activity, also display an LGMD2A-like phenotype, indicating that compromised calpain 3 protease activity rather than altered calpain structure is the more important contributor to the pathology of LGMD2A (Ono *et al.*, 1998).

Subsequent analyses of many additional families have so far identified numerous pathogenic and polymorphic mutations in *CAPN3* (Richard *et al.*, 1999; Saenz *et al.*, 2005). However, no mutational hot spot has been claimed for the disease, so it is difficult to make a genetic diagnosis of LGMD2A. A total of 2530 mutations, including 456 unique ones, have been reported in the *CAPN3* gene so far. Among *CAPN3* gene mutations, approximately 62.7% are nucleotide substitutions, of which, 60.3% are missense mutations, and the rest (37.8%) are pathogenic mutations. The association of LGMD2A with *CAPN3* mutations represents the first and so far the only example of a clear cause–effect relationship between human disease and calpain gene mutations (Sorimachi *et al.*, 2011).

Calpains in the Gastrointestinal Tract

Calpains 8 and 9 in the gastrointestinal tract are mainly expressed in surface mucus cells lining the gastric pits in the stomach, and in lesser amounts in the goblet cells of the intestines (Sorimachi *et al.*, 1993; Hata *et al.*, 2006). Calpain 8 is most similar to calpain 2, having a 62% identity in amino acid sequence with the conventional calpain. However, unlike

conventional calpains, the Ca^{2+} -dependent autolytic and catalytic activities of calpain 8 do not require the regulatory subunit, CAPNS1/30K (Hata *et al.*, 2007). Calpain 9, on the other hand, shares an approximately equal amino acid sequence identity with most other calpains, suggesting that this calpain subtype is closest to the ancestral calpain form (Lee *et al.*, 1998). Recombinant human calpain 9 requires CAPNS1/30K for its Ca^{2+} -dependent activity *in vitro*, and this activity can be inhibited by calpastatin and other Cys protease inhibitors (Lee *et al.*, 1999).

The properties of calpain 8 and calpain 9 *in vivo*, however, could differ greatly from those that have been observed *in vitro*. Analysis of *Capn8*^{-/-} and *Capn9*^{-/-} mouse models has revealed that neither calpain 8 nor calpain 9 forms a stable complex with CAPNS1/30K *in vivo*. Instead, they form a hybrid calpain 8/calpain 9 heterodimer referred to as gastric calpain (G-calpain) (Hata *et al.*, 2010). Disruption of either *Capn8* or *Capn9* was observed to down-regulate the other molecule in the pair, suggesting a co-dependency of the two calpains for stability and the proper function. Although neither *Capn8*^{-/-} nor *Capn9*^{-/-} mice display obvious gastric pathologies under normal conditions, the knockout mice are significantly more susceptible to ethanol-induced gastric ulcers (Hata *et al.*, 2010). *Capn8* knock-in (*Capn8*^{CS/CS}) mice expressing a structurally intact but protease-inactive calpain 8 mutant are also more susceptible to stress-induced gastric ulcers compared with wild type mice. The localization of calpain 8 and 9 in mucus-secreting cells, and the association of gastric ulcers with their disruption suggest that these calpains, coupled together to form heterodimeric G-calpain, play important roles in gastric mucosal defense (Hata *et al.*, 2010; Table 1). Additional reported functions for calpain 9 include an involvement in neoplastic transformation and tumorigenesis (Liu *et al.*, 2000), and in adhesion molecule-induced lumen formation in the mammary gland (Chen *et al.*, 2010).

A search of the single nucleotide polymorphism (SNP) database has revealed several CAPN8 and CAPN9 SNPs that result in amino acid substitutions (Hata *et al.*, 2010). Further *in vitro* studies showed that some of these substitutions are associated with the impaired proteolytic activity of G-calpain. Additional studies are needed to further explore the possibility of a relationship between CAPN8 and CAPN9 SNPs and the susceptibility to gastrointestinal disorders.

Calpains in the Endocrine System

Human calpain 10 is a ubiquitously expressed non-classical calpain that lacks PEF(L) domains but instead has two C2L domains in tandem at the C-terminus (Figure 1). In 2000, a large-scale genetic association study using haplotype analysis performed in Mexican Americans and a Northern European population from the Botnia region of Finland reported that a single nucleotide polymorphism (SNP-43) within intron 3 of CAPN10 is a risk factor for type 2 (i.e., non-insulin-dependent) diabetes mellitus, (NIDDM) (Horikawa *et al.*, 2000; Horikawa, 2006; Table 1). Subsequent genetic association studies performed in various populations (Horikawa, 2006; e.g., Indian (Baier *et al.*, 2000; British/Irish (Evans *et al.*, 2001); African-American (Garant *et al.*, 2002); Polish (Malecki *et al.*, 2002);

Finnish/Botnia (Orho-Melander *et al.*, 2002)) confirmed CAPN10 as a susceptibility gene for NIDDM and also reported several tag SNPs (including SNP-43, -44, -19, and -63) within CAPN10 as putative risk factors for NIDDM (Horikawa, 2006). Clinical studies in Pima Indians found that individuals with G/G homozygotes in SNP-43 have a reduced CAPN10 mRNA expression level and decreased rate of oxidative utilization of glucose in their skeletal muscle, indicating that this SNP may increase susceptibility to NIDDM by decreasing the rate of insulin-mediated glucose turnover (Baier *et al.*, 2000). However, the molecular mechanisms underlying the association of the reported tag SNPs within CAPN10 with susceptibility to NIDDM remain unclear.

Conclusion

The calpain system, unlike other eukaryotic proteolytic systems such as autophagolysosomes and proteasomes, engages in only a limited proteolysis of its substrates to create new signaling molecules with specific intracellular functions downstream of calpain activation by calcium. In this way, the calpain system shares a greater similarity with other enzymatically activated signaling systems (such a kinase dependent ones) than it does to mechanisms for complete protein breakdown. With a variety of enzymatic and regulatory subunits coded by separate genes, the calpain family has been shown to play a role in a large number of both very basic cellular processes such as survival, apoptosis, necrosis, migration, adhesion, and in cell type-specific functions. Thus, the inappropriate activation of calpain has been identified or suspected in a wide range of clinical disorders, and the use of specific calpain inhibitors has been proposed to be an effective therapeutic strategy. Nonetheless, many open questions regarding the calpain proteolytic system remain, including the extent of its involvement in numerous cellular processes not described above. Given the ubiquity of the system and its strict regulation by Ca^{2+} and other factors, it is not hard to imagine that calpains will soon be recognized both as critical players in the normal maintenance of cellular function, and as key participants in the progression of diseases when calpain regulation fails.

Aspartic Peptidases

Proteolytic enzymes (peptidases, proteases) are of great relevance to biology, medicine, and biotechnology. Based on the nature of their catalytic residues and the homologous sets of their sequences, peptidases are now classified into nine families; aspartic- (A), cysteine- (C), glutamic- (G), metallo- (M), asparagine- (N), mixed- (P), serine- (S), threonine- (T) and unknown- (U) peptidases. Aspartic peptidases are widely distributed among vertebrates, yeast, plants, nematodes, fungi, protozoa, parasites, and retrovirus and have received enormous interest because their abnormal expression and uncontrolled activities are closely linked to various human diseases. Extra efforts have thus been made to develop clinically active inhibitors of each peptidase for the treatment of such diseases.

According to the MEROPS database, aspartic peptidases are further classified into 16 different subfamilies, based on their amino acid sequence homology followed by their evolutionary relationship and tertiary structures. The A1 family peptidase includes most of aspartic endopeptidases found in higher organisms and has the catalytic Asp residues within an Asp-Thr/Ser-Gly motif between both N- and C-terminal lobes of the molecules. The two lobes have similar structures, despite very little amino acid sequence similarity. Most of the A1 family peptidases display the maximum activity at acid pH, although some such as renin are active at neutral pH, and are more or less strongly inhibited by pepstatin. This family is also divided into secretory and nonsecretory groups. The former includes pepsin, gastricsin, chymosin, renin, and candida-pepsin SAP1, whereas the latter is represented by cathepsin D, cathepsin E, and β -secretase. The former members have not only well-defined physiological functions but also the possible implications in various pathological conditions, for example, cancer and hypertension. Most of the latter members are also associated with various human diseases, but mechanistic insights into how each enzyme links to pathological processes peculiar to each enzyme are not well addressed. Among them, pepsin A is well-known to contribute to proteolysis of food proteins in the vertebrate stomach, whereas cathepsins D and E serve for nonspecific and/or specific proteolysis in the endosomal/lysosomal system or the extracellular spaces. β -Secretase (BACE1, β -site amyloid precursor protein (APP) cleaving enzyme 1, or memapsin 2) is a membrane-bound aspartic peptidase and is known to cleave the type I transmembrane APP to generate a secreted form of truncated APP and a membrane-anchored C-terminal fragment of 99 amino acids (C99). C99 is further processed by another membrane peptidase γ -secretase, composed of four transmembrane proteins (presenilin, nicastrin, Pen2, and Aph1), to yield a p3 fragment and the neurotoxic amyloid β peptide (A β). Since

accumulation of A β in the brain is closely associated with the pathogenesis of Alzheimer's disease (AD), strategies to inhibit A β formation are believed to prove beneficial for AD treatment. To date, a number of inhibitors of β -secretase to prevent A β generation have been developed.

The pepsin subfamily of the A1 family (clan A1A) is significantly related to the retropepsin subfamily of the A2 family (clan A2A). Human immunodeficiency virus type-1 (HIV-1) retropepsin is a representative aspartic peptidase in the A2A subfamily, essential for processing newly synthesized *gag-pol* polyproteins at eight sites, mostly with hydrophobic residues in P1 and P'1, thereby generating the mature protein components of an infectious HIV virion. Hence this peptidase is indispensable for the life-cycle of HIV. By X-ray crystallography, this peptidase is shown to exist as a catalytically active homodimer, with each subunit made up of 99 amino acids. The active site of HIV-1 retropepsin lies between the two subunits containing one Asp-Thr-Gly motif for each. Each motif contributes to one of the pair of catalytic Asp residues (reviewed in, Navia and MaKeever, 2006; Louis *et al.*, 2007; Patel *et al.*, 2013). Therefore, the retropepsin is believed to be an important drug target for AIDS. Actually, several promising HIV-1 peptidase inhibitors have entered human clinical trials.

Cathepsin E

Historical Background

Cathepsin E was first identified in aqueous extract of rabbit bone marrow by Lapresle and Webb (1962), where it exhibited the maximal activity at pH 2.5 on human serum albumin and a higher molecular weight than the analogous cathepsin D. For 15 years since then the existence of this enzyme had long been an object of discussion. This argument seemed to reach a conclusion by the identification and characterization of two analogous aspartic peptidases, cathepsin E-like enzyme (Yamamoto *et al.*, 1978) and cathepsin D (Yamamoto *et al.*, 1979) in rat spleen and subsequently by showing clear differences in their immunochemical properties (Yamamoto *et al.*, 1980). In those days, the analogous proteinases were also isolated from a variety of sources and called by different designations, including cathepsin D-type proteases (lymphoid tissues) (Yago and Bowers, 1975), cathepsin D-like acid proteinase and slow moving proteinase (gastric mucosa) (Kageyama and Takahashi, 1980; Muto *et al.*, 1983; Samloff *et al.*, 1987), erythrocyte membrane acid proteinase (EMAP) (erythrocyte membranes) (Yamamoto and Marchesi, 1984; Takeda *et al.*, 1986), and cathepsin E (epidermis) (Hara *et al.*, 1993). Later, on the basis of biochemical and immunochemical analyses, these enzymes were proved to be identical

(Tarasova *et al.*, 1986; Yamamoto *et al.*, 1987; Muto *et al.*, 1987; Jupp *et al.*, 1988) and ultimately referred to as cathepsin E. Shortly after these studies, the cDNA clone encoding human cathepsin E was isolated and sequenced, and its chromosomal localization and sequence homology to other aspartic peptidases were defined (Azuma *et al.*, 1989). At this point, cathepsin E established its position as an independent peptidase.

Tissue Distribution and Cellular Localization

Differing from the definite localization of other related aspartic peptidases, cathepsin E has a limited distribution in certain cell types, including the immune system cells such as lymphocytes, macrophages, dendritic cells, microglia, and Langerhans cells and the rapidly regenerating cells such as gastric mucosal cells, epidermal keratinocytes (reviewed in, Yasuda *et al.*, 1999a,b; Zaidi and Kalbacher, 2008; Chlabicz *et al.*, 2011; Yamamoto *et al.*, 2012), and mammary epithelial cells (Kawakubo *et al.*, 2014). The cellular localization of cathepsin E also varies with different cell types. In antigen presenting cells (APC) such as microglia (Sastradipura *et al.*, 1998; Nishioku *et al.*, 2002), macrophages (Yanagawa *et al.*, 2007) and dendritic cells (Chain *et al.*, 2005), mast cells (Henningsson *et al.*, 2005), and mammary epithelial cells (Kawakubo *et al.*, 2014), cathepsin E is mainly confined to endosomal structures. The association of cathepsin E with plasma membranes is observed in erythrocytes (Yamamoto and Marchesi, 1984; Takeda *et al.*, 1986), intracellular canaliculi of gastric parietal cells, renal proximal tubule cells, bile canaliculi of hepatic cells (Saku *et al.*, 1991), and osteoclasts (Yoshimine *et al.*, 1995). The enzyme is also detected in the endoplasmic reticulum and/or Golgi complex (Samloff *et al.*, 1987; Fiocca *et al.*, 1990; Saku *et al.*, 1991; Finzi *et al.*, 1993; Sastradipura *et al.*, 1998), and the cytoplasmic matrix (Saku *et al.*, 1991; Sakai *et al.*, 1992; Tsukuba *et al.*, 1993; Finley and Kornfeld, 1994). In addition to its intracellular localization, cathepsin E is secreted extracellularly from activated APC (Yanagawa *et al.*, 2006), mammary epithelial cells (Kawakubo *et al.*, 2014), and cancer cells (Kawakubo *et al.*, 2007). Such strategic expression and localization of cathepsin E have been suggested its association with specific functions in the individual cell types.

Regulation of Cathepsin E Gene Expression

To date, the nucleotide sequence of the cDNA encoding procathepsin E has been defined in human (Azuma *et al.*, 1989), guinea pig (Kageyama *et al.*, 1992), rabbit (Kageyama, 1993), rat (Okamoto *et al.*, 1995), and mouse (Tatnell *et al.*, 1997). The promoter region of cathepsin E gene has some characteristic features different from those of other analogous aspartic peptidases, which seems to be linked to its limited distribution. The promoter region of cathepsin E gene had no TATA box that offers a binding site for transcription factor IID (Azuma *et al.*, 1992; Tatnell *et al.*, 1998). The tissue- and cell-specific transcription regulation of cathepsin E gene was also suggested to be associated in part with a decreased level of methylation in the gene region (Tsukada *et al.*, 1992) or the balance between the positive effect of cell-specific transcription

factors such as GATA1 and PU1 and the negative influence of the ubiquitous YY1 factor (Cook *et al.*, 2001). Cathepsin E transcription may also be regulated positively by PU1 and p300 and negatively by Class II transactivator (Yee *et al.*, 2004). Additionally, it has recently been demonstrated that the expression of murine cathepsin E gene is positively regulated by binding of the transcription factor Sp1 to its promoter region (Okamoto *et al.*, 2012). Characteristics of the transcripts of mouse cathepsin E gene are shown in Figure 1.

Biosynthesis and Trafficking

Cell-specific processing and trafficking

Cathepsin E exists as a homodimer of two catalytic active monomers with a molecular mass of 42 kDa and is N-glycosylated with high mannose- and/or complex-type oligosaccharides. Cathepsin E is present predominantly as the homodimer and partly as the catalytically active monomer. The dimer and monomer forms are easily interconverted by reducing agents such as 2-mercaptoethanol and cysteine *in vitro* (Kageyama *et al.*, 1992). Although the catalytic properties were indistinguishable between the both forms, the dimer form was more stable to pH and temperature changes than the monomer form (Kageyama *et al.*, 1992; Fowler *et al.*, 1995; Tsukuba *et al.*, 1996). Accordingly, the dimerization is thought to be necessary for structural stabilization of this molecule, but not for its proper folding, correct intracellular localization, and carbohydrate modification (Tsukuba *et al.*, 1996).

Although the potential N-glycosylation site near the N-terminal region is conserved in all of the species tested, its number near the C-terminal regions varies with different species. Human and rabbit cathepsin E has one potential N-glycosylation site at the N-terminal region only. Besides the N-terminal N-glycosylation site, rat and guinea pig cathepsin E has an additional N-glycosylation site at the C-terminal region. Mouse cathepsin E has two additional N-glycosylation sites in the C-terminal region. Cathepsin E from erythrocytes (human and rat), microglia, and thymocytes (rat) is N-glycosylated with complex-type oligosaccharides, whereas the enzyme from spleen and stomach (rat) has high-mannose-type oligosaccharides. Therefore, the nature of its oligosaccharide chains may be cell-specific or vary with its cellular localization. By pulse-chase experiments with ³⁵S-methionine, cathepsin E was shown to be initially synthesized on the membrane-bound ribosomes as a preproenzyme and then undergo different proteolytic and glycolytic processing depending on cell types before being sorted to its appropriate cellular destinations (reviewed in, Yamamoto *et al.*, 1994, 1997; Yamamoto, 1999). In rat macrophages (Yamamoto *et al.*, 1997) and microglia (Sastradipura *et al.*, 1998), procathepsin E undergoes proteolytic processing to yield the mature enzyme composing of two active monomers via the intermediate form. In these cell types, procathepsin E is initially N-glycosylated with high mannose-type oligosaccharides and then converted to the mature enzyme with complex-type oligosaccharides. In rat thymocytes and mouse Friend erythroleukemia cells, procathepsin E is initially synthesized as a 46-kDa monomer and converted to the homodimer and then processed to the 44-kDa intermediate form with complex-type oligosaccharides, which

Figure 1 Characterization of the transcripts of mouse cathepsin E gene. (a) A schematic diagram of two types of cathepsin E transcripts in wild-type mice. Total RNA from various tissues of wild type (C57BL/6 J) and cathepsin E-null mice was analyzed by RT-PCR using a forward primer for noncoding exon (N) and a reverse primer in exon 1. The RNA from most of wild-type tissues such as spleen and lung reacted with the primers containing the noncoding exon (spleen-type), whereas the RNA from the stomach did not (stomach-type). The RNA from either type of tissues reacted with downstream primers containing exons 6–7. Numbers in each column indicate noncoding and coding exon. (b) Total RNAs were isolated from spleen and stomach of the wild type and cathepsin E-null mice. RT-PCR was performed with 1 μ g of total RNA. The amplified DNA was visualized on 2% agarose gel. W and KO indicate wild type and cathepsin E-null mice. (c) Binding sites of three possible transcription factors Sp1, Ap-1, and cEts-1 in cathepsin E gene. (d) A chromatin immunoprecipitation (ChIP) assay of the *in vivo* recruitment of Sp1, Ap-1, and cEts-1 to the promoter region of cathepsin E gene in human gastric adenocarcinoma (AGS) cells. DNA purified from the immunoprecipitated chromatin was amplified by PCR. (e) Western blot analysis of cathepsin E protein in wild-type and Sp1-overexpressing AGS cells. The protein from AGS cells and the cells stably transfected with Sp1 was collected and analyzed by a Western blotting analysis. β -Actin was used as a loading control. The density of each protein in Sp1-overexpressing AGS cells is expressed as relative ratios to that in the control cells, as shown below each column.

retains in the *trans*-Golgi region till the cells are activated in response to certain stimuli such as steroid hormone (Yamamoto *et al.*, 1994, 1997; Nishishita *et al.*, 1996). In Chinese hamster ovary cells and normal rat kidney cells expressing exogenous human and rat cathepsin E, respectively, procathepsin E was proteolytically processed to the intermediate form with high mannose-type oligosaccharides and stably retained in the ER and the *cis*- or *medial*-Golgi region (Tsukuba *et al.*, 1993; Yamamoto *et al.*, 1997; Yamamoto, 1999). In mouse L cells and monkey Cos 1 cells expressing human cathepsin E, the expressed protein was exclusively confined to the ER as the proenzyme bearing high mannose-type oligosaccharide chains and the first 48 amino acids of mature cathepsin E was responsible for its retention in the ER (Finley and Kornfeld, 1994). Studies with various cathepsin E mutants also revealed a vital role of propeptide in the correct folding, maturation, and targeting to its final destinations (Yasuda *et al.*, 2005a; Tsukuba *et al.*, 2006a). N-Glycosylation of cathepsin E was also important for its proper folding upon changes in temperature, pH, and redox state, and the complex-type oligosaccharides contribute to the completion of the tertiary structure to maintain its active conformation in the weakly acidic pH environments (Yasuda *et al.*, 1999a).

Autoactivation

Both natural and recombinant procathepsin E are synthesized as catalytically inactive enzymes, but they are rapidly

converted to the mature enzyme by a brief acid treatment, accompanying proteolytic removal of the propeptide (reviewed in, Yamamoto, 1999). Although procathepsin D (Conner, 1989) and pepsinogens (Athauda *et al.*, 1989) were activated through their intermediate forms, procathepsin E was directly converted to the mature form depending on its protein concentration and completely inhibited by pepstatin A (Athauda *et al.*, 1991a; Takeda-Ezaki and Yamamoto, 1993). The results thus indicate that the intermolecular reaction is predominantly involved in one-step activation of the enzyme (reviewed in, Yamamoto, 1995, 1999).

Substrates

Based on nonspecific degradation profiles of various protein substrates in acidic pH, cathepsin E has long been thought to serve as house-keeping enzymes for the acquisition of amino acids. On the other hand, cathepsin E is known to specifically cleave various natural proteins such as α 2-macroglobulin (Shibata *et al.*, 2003), reduced-carboxymethylated ribonuclease A (Athauda and Takahashi, 2002) and big endothelin (Lees *et al.*, 1990), and several biologically active peptides such as substance P, neurokinin (Kageyama, 1993; Kageyama *et al.*, 1995), and oxidized insulin B chain (Athauda *et al.*, 1991b), suggesting that it possesses more specific functions. On the basis of substrate cleavage specificity, many attempts have also been made to construct convenient and selective substrates for this enzyme. To date, several synthetic substrates of cathepsin E have been

Table 1 Kinetic parameters for hydrolysis by cathepsin E of peptide substrates

synthesized (Rao-Naik *et al.*, 1995; Yasuda *et al.*, 1999b, 2005b; Abd-Elgalil and Tung, 2010). The kinetic parameters for the hydrolysis of various substrates by cathepsin E, as well as cathepsin D and pepsin A, are summarized in Table 1.

Activators

Although cathepsin E has only a little activity at pH values above 5.5, it was shown to exhibit virtually full activity on synthetic substrates and casein at pH 5.8 in the presence of ATP, where ATP is suggested to stabilize the molecule in such a way to maintain its active conformation (Thomas *et al.*, 1989a). Among nucleotides and inorganic phosphates, GTP and ATP were shown to most profoundly activate cathepsin E activity (about 3.5-fold that in the absence of each compound) (Yamamoto *et al.*, 1991). Recently, some peptide aptamers capable of enhancing cathepsin E activity at neutral pH have been developed by an *in vitro* evolution method based on an inverse substrate function-link-selection technique (Biyani *et al.*, 2011). Of these, the IGCEERSFPNIIIG peptide was shown to activate cathepsin E activity up to 2.6-fold that without the compound.

Inhibitors

Pepstatin is a peptide inhibitor isolated from cultures of *Actinomyces* by Umezawa *et al.* (1970) and is widely used as a potent inhibitor of cathepsin E. Because this inhibitor is a general inhibitor of aspartic peptidases of the A1 family, however, it is not specific for cathepsin E. Also, α 2-macroglobulin

was found to be a nonspecific protein inhibitor for cathepsin E (Thomas *et al.*, 1989b). The degradation of reduced and carboxymethylated ribonuclease A by cathepsin E at pH 5.5 was completely blocked by α 2-macroglobulin, but that of oxidized insulin B chain was not inhibited by this protein (Athauda *et al.*, 1993). The cleavage of peptide substrates such as Pro-Pro-Thr-Ile-Phe-Phe-(4-NO₂)-Arg-Leu by cathepsin E at pH 6.2 was also scarcely inhibited by α 2-macroglobulin (Thomas *et al.*, 1989b). In the course of the study to assess the involvement of cathepsin E in disruption of structural and functional integrity of α 2-macroglobulin in the endolysosome system, this inhibitor was found to be selectively and rapidly cleaved at the Phe811-Leu812 bond in about 100mer downstream of the bait region by cathepsin E below pH 5.0 (Shibata *et al.*, 2003). The natural protein inhibitor specific for cathepsin E, termed *Ascaris* pepsin inhibitor, was first isolated from the roundworm *Ascaris lumbricoides* (Abu-Ereish and Peanasky, 1974; Keilová and Tomášek, 1972). Recently, Kitamura *et al.* (2009) isolated a series of inhibitory peptide aptamers for cathepsin E by using the *in vivo* evolution method and identified the peptide SCGGIIISICIA (Pi101) as the most potent inhibitor of the enzyme (*K_i*; 5 nM) without affecting cathepsin D.

Pathophysiological Functions

Roles in immune responses

Proteolytic processing of the invariant chain (Ii) to class II-associated Ii peptide (CLIP) is known to be essential for the MHC class II antigen presentation. The cleavage of Ii has been

shown to be initiated by cathepsins D and/or E (Maric *et al.*, 1994; Kageyama *et al.*, 1996) and subsequently processed to generate CLIP by cysteine cathepsins L and S in the thymus and the peripheral lymphoid organs, respectively (reviewed in, Chapman, 2006; Colbert *et al.*, 2009). The cysteine cathepsin F is also implicated in CLIP generation in peripheral macrophages (Shi *et al.*, 2000). On the other hand, exogenous antigens, such as ovalbumin (Bennett *et al.*, 1992; Nishioku *et al.*, 2002; Chain *et al.*, 2005), myoglobin (Moss *et al.*, 2005), and tetanus toxin (Burster *et al.*, 2008), were shown to be processed by cathepsin E in various APC. An equivocal role of cathepsin E in class II ovalbumin presentation in macrophages was further substantiated by studies using cathepsin E-deficient macrophages (Kakehashi *et al.*, 2007). Interestingly, although the class II ovalbumin presentation in macrophages was markedly decreased by cathepsin E deficiency, that was enhanced in cathepsin E-deficient dendritic cells, partly due to enhanced phagocytic activity and increased expression of co-stimulatory molecules such as CD86, CD80, and CD40 in these cells (Kakehashi *et al.*, 2007).

A close link between cathepsin E function and immune responses was also supported by the increased expression of cathepsin E in microglia by treatment with interferon- γ without affecting the expression of cathepsins D, B, L, and S (Nishioku *et al.*, 2002). Consistently, the increased expression, maturation, and secretion of cathepsin E in macrophages were also induced by treatment with interferon- γ and lipopolysaccharide (Yanagawa *et al.*, 2006). Notably, cathepsin E-null mice spontaneously developed atopic dermatitis-like skin lesions when kept under conventional conditions (Tsukuba *et al.*, 2003). These mice, like atopic dermatitis patients, showed the strong polarization of naïve T cells to Th2 cells and systemic accumulation of IL-18 and IL-1 β accompanied by enhanced production of IL-4, IL-5, and IgE. In this regard, the significantly decreased cathepsin E expression was also observed in both atopic dermatitis patients and the animal model of NC/Nga mice. Together, considering that the expression of MHC class II molecules in dendritic cells is lower in NC/Nga mice than in BALB/c and DBA mice (Sakai *et al.*, 2012), cathepsin E deficiency is likely to cause aberrant Th2-type immune responses. Additionally, cathepsin E deficiency dramatically increased susceptibility to bacterial infection (Tsukuba *et al.*, 2006b). This is likely to be associated with decreased expression of multiple cell surface Toll-like receptors in macrophages. Similarly, the cell surface expression of chemotactic receptors (CCR-2 and FPRs) and adhesion receptors (CD18 and CD29) was significantly decreased by cathepsin E-deficient macrophages (Tsukuba *et al.*, 2009), thereby leading to their decreased chemotactic and adhesion abilities. In this regard, it has been shown that the impaired adipose tissue development in cathepsin E-null mice fed on a high-fat diet, accompanying reduced body weight and defective development of white and brown adipose tissues, is associated partly with the decreased infiltration of macrophages into white adipose tissues (Kadowaki *et al.*, 2014).

Importantly, cathepsin E deficiency was also shown to induce a novel form of lysosomal storage disorder in macrophages, but not in dendritic cells, which is accompanied by accumulation of major lysosomal membrane sialoglycoproteins such as LAMP-1 and LAMP-2 and elevation of lysosomal

pH (Yanagawa *et al.*, 2007). Additionally, cathepsin E deficiency caused the impairment of the autophagosome-lysosome fusion event in macrophages, accompanying accumulation of aberrant mitochondria and increased oxidative stress (Tsukuba *et al.*, 2013). A schematic representation of the effects of cathepsin E deficiency on the nature and functions of macrophages is shown in Figure 2.

It is noteworthy that cathepsin E expression at protein and message levels in hemopoietic cells, but not in gut, from C57BL/6 J mice is apparently lower than those from 129S2/Sv or Balb/c mice and causes the impairment of ovalbumin presentation in dendritic cells (Tulone *et al.*, 2007). The results suggested that C57BL/6 J mice exhibit tissue-specific cathepsin E deficiency and have poor immune responses to some antigens. Cathepsin E-null mice described here were generated using 129S2/Sv-derived embryonic stem cells and then backcrossed onto the C57BL/6 J strain. Hence, a question arose as to whether the pleiotropic phenotype of cathepsin E-null mice might be autonomous or secondary to other *in vivo* defects. However, considering that, both cathepsin E-null 129S2/Sv and C57BL/6 J mice similarly developed AD-like skin lesions and exhibited the enhanced susceptibility to bacterial infection and that ovalbumin presentation in dendritic cells, but not macrophages, was significantly enhanced by cathepsin E deficiency, it is likely that the observed pleiotropic phenotypes of cathepsin E-null mice are independent of mouse strains.

Roles in Cell Growth and Differentiation

Role in skin

It is generally accepted that dermatological disorders ranging from minor cosmetic problems to life-threatening conditions are commonly due to abnormal differentiation of keratinocytes, a major component of a stratified and keratinized epithelium. In human and rat epidermis, cathepsin E was shown to be localized mainly in keratinocytes and in close vicinity to the inner root sheath of hair follicles (Kawakubo *et al.*, 2011). Remarkably, cathepsin E deficiency caused abnormal keratinocyte differentiation in the epidermis and hair follicle of mice, accompanying the significant expansion of corium and the reduction of subcutaneous tissue and hair follicle. Additionally, cathepsin E deficiency induced significantly reduced expression and altered localization of keratinocyte differentiation-induced proteins, such as keratin 1 and loricrin. The role of cathepsin E in regulation of the epidermal differentiation marker proteins was further verified by experiments with primary cultures of keratinocytes from three different genotypes of mice, wild-type, cathepsin E-null, and cathepsin E-overexpressing transgenic mice. Only cathepsin E-null mice caused delayed differentiation accompanying the reduced expression or the ectopic localization of the differentiation marker proteins. On the contrary, cathepsin E-overexpressing animals enhanced the keratinocyte terminal differentiation process. Cathepsin E is thus likely to be associated with proper epidermis formation and homeostasis.

Roles in gastric development and cancer

The role of cathepsin E in early developmental stages was first demonstrated in various fetal rat tissues (Kageyama *et al.*, 1998).

Figure 2 A schematic representation for the conditions manifested in macrophages by cathepsin E deficiency.

Although cathepsin D increased gradually in all the tissues during fetal development, cathepsin E was differentially expressed in various tissues at fetal developmental stages. Cathepsin E expression in liver increased rapidly from a 13-day gestation fetal stage and decreased gradually at later fetal stages, whereas that in stomach, spleen, and thymus began to increase at later fetal stage or the infant stage. Cathepsin E is thus likely to serve as a growth factor in fetal liver and gastrointestinal tissues and to stimulate the development of these tissues. On the other hand, cathepsin E is known to be intensely expressed in human and rat gastric foveolar epithelial cells (Shiraishi *et al.*, 1988; Sakai *et al.*, 1989) and its expression is altered in various gastric cancer types (Saku *et al.*, 1990; Fiocca *et al.*, 1990; Konno-Shimizu *et al.*, 2013). Cathepsin E was expressed mostly in poorly differentiated adenocarcinoma and signet-ring carcinoma, whereas it was barely detectable in mucinous adenocarcinoma, papillary adenocarcinoma, and dysplasia. A considerable part of specimens for moderately differentiated adenocarcinoma, papillary adenocarcinoma, and intestinal metaplasia exhibited cathepsin E expression. Therefore, cathepsin E is suggested to serve as a marker for gastric differentiation and signet-ring carcinoma.

Diagnostic and prognostic values in breast cancer

Cathepsin E is known to be up-regulated and secreted in certain types of normal cells (e.g., activated macrophages and mammary epithelial cells) and abnormal cancer cells. Recent studies have suggested the clinical utility of cathepsin E as a potential diagnostic or prognostic marker in various human cancers, although its clinical significance is controversial (reviewed in, Yamamoto *et al.*, 2012). This conflation is likely to arise from differences in expression levels of some

nonfunctional cathepsin E proteins between cancer cell types, because its expression levels were determined mostly by immunological methods such as immunohistochemistry, tissue microarray, and enzyme-linked immunosorbent assay (ELISA) or by gene expression profiling analysis. In fact, the recent study with patients with breast cancer (BC) showed that serum levels of cathepsin E determined by ELISA were not consistent with those by activity measurement using the synthetic substrate KYS-1 (Kawakubo *et al.*, 2014). The activity levels alone were negatively associated with the stages and progression of this disease. Univariate and multivariate analyses also revealed that the serum levels of cathepsin E activity were significantly correlated with favorable prognostic outcomes of the patients, indicating that the serum cathepsin E activity must serve as an independent biomarker for prognosis of BC. The functional link of cathepsin E expression with mammary carcinogenesis was further verified by *in vivo* and *in vitro* studies with female mice exhibiting different levels of cathepsin E expression. Surprisingly, multiparous cathepsin E-null mice spontaneously developed mammary tumors at a high frequency in an age-dependent manner, concomitant with morphological transformation, and altered growth characteristics of the mammary glands. However, virgin cathepsin E-null mice, like wild-type and cathepsin E-overexpressing transgenic mice, did not develop mammary tumors at all. The observed alterations in mammary glands of multiparous cathepsin E-null mice were associated with epithelial-mesenchymal transition and the activation of canonical Wnt/ β -catenin pathway in mammary cells, where the nuclear translocation and accumulation of noncanonical Wnt5a, a tumor suppressor in mammary carcinogenesis, were strongly induced, thereby resulting in the aberrant trafficking, maturation and secretion of Wnt5a, and

Figure 3 A schematic representation of the possible mechanisms for mammary carcinogenesis by cathepsin E deficiency.

the impairment of the related Wnt5a/Ror2 signaling. Accordingly, cathepsin E is likely to contribute to normal growth and development of mammary glands through proper trafficking and secretion of Wnt5a (Figure 3).

Suppression of cancer progression

It has recently demonstrated that cathepsin E, unlike other peptidases such as cathepsin D and cysteine cathepsins, has the anticancer ability through its manifold functions. These include the induction of tumor cell-specific apoptosis through the generation of tumor necrosis factor-related apoptosis ligand (TRAIL) from the surface of cancer cells, the cytotoxic effects of the infiltrated and activated immune cells, and the production of angiogenesis inhibitor such as endostatin in the vicinity of tumors (reviewed in, Yamamoto *et al.*, 2012). Cathepsin E is also shown to enhance the anticancer activity of doxorubicin on human prostate cancer cells showing resistance to TRAIL-mediated apoptosis by down-regulation of c-FLIP, a FLICE inhibitory protein, and decreased cancer cell proliferation (Yasukochi *et al.*, 2010).

Roles in the neuronal system

Cathepsin E is barely detectable in any brain regions of young rats and mice and is markedly increased in the cerebral cortex and neostriatum of aged rats and in the brain stem of aged mice (Nakanishi *et al.*, 1994; Amano *et al.*, 1995). Up-regulation of cathepsin E in both neurons and microglial cells in the central nervous system was also observed during neuropathological changes associated with transient forebrain ischemia (Nakanishi *et al.*, 1993) and kainate-induced epilepsy (Tominaga *et al.*, 1998), as well in aging. The ischemia-induced up-regulation was mainly observed in degenerating neurons and activated microglia in the hippocampal CA1 region. In aged neurons, highly expressed cathepsin E was co-localized with lipofuscin and APP C-terminal fragments, suggesting its association with lipofuscinosis and altered intracellular APP metabolism (Nakanishi *et al.*, 1997). Additionally, cathepsin E in the brains of patients with AD was observed in senile plaques, besides cerebral microvessels and

microglia (Bernstein and Wiederanders, 1994). Consequently, it is more likely that cathepsin E is involved in the process of neurodegeneration in AD. Interestingly, although cathepsin E-null mice were behaviorally normal when housed communally, they became more aggressive compared with the wild-type littermates when housed individually in a single cage, which was accompanied by an increase in substance P in amygdala, hypothalamus, and periaqueductal gray (Shigematsu *et al.*, 2008). The increased aggressive response was reduced by pretreatment with a neurokinin-1-specific antagonist, suggesting that cathepsin E is associated with the substance P/neurokinin-1 signaling system and thereby regulates the aggressive response of the animals to stressors.

Conclusion Remarks

The review describes the basic information and major functional roles of cathepsin E. The unique and strategic expression and localization of cathepsin E seem likely to be associated with specific functions of each cell type. Cathepsin E has been shown to be involved in a variety of physiological functions, including processing of secretory proteins in various cell types, degradation of biologically active peptide, exogenous antigen processing and presentation, host defense against bacterial infection, and chemotaxis and adhesion of the immune system cells. Growing evidence also indicate that cathepsin E has a potent anticancer activity through multiple mechanisms. In this regard, it has been demonstrated that regression of cathepsin E expression increases the risk of mammary carcinogenesis and links to poor prognosis in BC. Furthermore, cathepsin E is shown to be increased in both neuron and microglia during neuropathological changes associated with aging, transient forebrain ischemia, and epilepsy.

Metalloproteases Meprin α and Meprin β in Health and Disease

C Tredup and C Becker-Pauly, University of Kiel, Kiel, Germany

© 2016 Elsevier Inc. All rights reserved.

Introduction

Meprins were first described by Judith Bond and colleagues in 1980 who discovered strong proteolytic activity in mouse and rat kidney that could not be assigned to any known protease (Beynon *et al.*, 1981). The term 'meprin' was created meaning metalloprotease from renal tissue.

At this time an interesting clinical observation was made when patients after pancreatic surgery still exhibited proteolytic activity against the so-called PABA-peptide (N-benzoyl-L-tyrosyl-p-aminobenzoic acid), a diagnostic marker for chymotrypsin activity (Sterchi *et al.*, 1983). Thereafter, the responsible protease was called PPH (PABA-peptide hydrolase). Later on, based on sequence similarities, PPH was renamed human meprin.

In mouse and man, two related proteases meprin α and meprin β exist that are encoded by different genes. The meprin α and meprin β genes in mice are located on chromosomes 17 and 18, respectively (Bond *et al.*, 1984), whereas human meprin α and meprin β are located on chromosomes 6 and 18, respectively (Bond *et al.*, 1995). Interestingly, the meprin α genes in rodents and mammals are in close proximity to the MHC H2 complex, which might be a link to immunological functions of these enzymes, discussed later in this article.

All phylogenetic analyses so far provided evidence that meprin metalloproteases evolved in vertebrates only (Becker-Pauly *et al.*, 2009). Although other MAM (meprin 5A protein tyrosine phosphatase μ) domain containing astacins are existing already in invertebrates it was demonstrated by Becker-Pauly and colleagues that these proteases, for example, HMP2 from *Hydra vulgaris* (Yan *et al.*, 2000), did not cluster in the same branch with meprins when comparing the sequences of many astacins from different species. Thus independent achievement of MAM domains by astacin proteases probably occurred several times. However, recent sequencing projects revealed that two different meprins already exist in *Ciona intestinalis*, also called vase tunicate, an animal that is a phylogenetic ancestor of vertebrates (Figure 1). These proteins contain not only a MAM but also a TRAF (tumor-necrosis-factor-receptor-associated factor) domain, indicating that this combination is the minimal requirement for the group of meprin metalloproteases. This finding opens new ideas about the biological functions of meprins, which may be associated with immunological processes and tissue development, as described later on.

Structural Features of Meprin α and Meprin β

Meprins belong to the astacin family of metalloproteases and the metzincin superfamily (Stocker *et al.*, 1995). As all members of the astacin family, meprin α and meprin β contain the characteristic zinc-binding motif HExxHxxGxxHxxxRxDR that stabilizes the central zinc ion. A conserved sequence in close

proximity to the active site cleft, namely the Met-turn, includes a tyrosine residue that serves as an additional zinc ligand. However, among astacins meprins exhibit unique structural properties.

Both meprin subunits are expressed as highly glycosylated, disulfide linked multi-domain proteins comprising an amino-terminal signal peptide, which directs the protease into the endoplasmatic reticulum (Figure 2(a)). The signal peptide is followed by the propeptide that keeps meprins in the inactive state. Therefore, upon secretion meprin α and meprin β undergo posttranslational modification to gain their full activity. The enzymatic removal of the propeptide can be carried out by several serine proteases, such as the members of the kallikrein-related peptidases (KLKs) (Ohler *et al.*, 2010). C-terminal of the propeptide there is an astacin-like protease domain, a MAM domain, a TRAF domain, an EGF (epidermal growth factor)-like domain, a transmembrane region, and finally a cytosolic tail follows. In contrast to meprin β , meprin α contains an additional domain, the so-called inserted domain, which is cleaved by furin during the secretory pathway (Figure 2(a)). This leads to the release of the soluble ectodomain of meprin α into the extracellular space. Interestingly, as demonstrated in Figure 1, such an inserted domain is missing in meprins from *Ciona intestinalis*. However, this is probably due to incomplete sequencing, since the signal peptides are not entirely annotated as well.

Human meprin α and meprin β are secreted as homo-dimers. Until recently, it was unrevealed how exactly these homo-dimers are stabilized. The crystal structure of meprin β nicely uncovered this question by showing that a single disulfide-bridge between MAM domains is sufficient to form a meprin α or a meprin β homo-dimer (Arolas *et al.*, 2012) (Figures 2(b) and 2(c)). Upon secretion, meprin α homo-dimers oligomerize non-covalently to huge complexes, which can reach a size of up to 6 MDa (Bertenshaw *et al.*, 2003). The lack of the 'inserted' domain leads to the expression of membrane-bound meprin β homo-dimers, which can be released from the cell surface by ectodomain shedding through the metalloproteases ADAM10 or ADAM17 (Hahn *et al.*, 2003; Jefferson *et al.*, 2013).

Inhibition of Meprin Metalloproteases

The mechanisms for regulation of protease's activity involve endogenous activators and inhibitors and an imbalance consequently leads to a range of pathologic events. Less is known about endogenous inhibitors of meprin α and meprin β . Fetuin-A, a negative acute-phase plasma protein has been identified as endogenous inhibitor for meprin α and meprin β activity (Hedrich *et al.*, 2010). Additionally, nephrosin which is a fetuin-A homologue from carp is able to inhibit the catalytic activity of both human meprins. Further, cystatin C has been shown to regulate the activity of meprin α but not of

Figure 2 Structure and cleavage specificity of meprins. (a) Cartoon of domain organization of meprins before proteolytic processing. Homodimers are linked by a disulfide-bridge between the MAM domains. Only meprin α/α contains an Inserted (I) domain, which is cleaved by furin in the secretory pathway. Meprin β/β can be shed from the cell surface by ADAM. PRO (propeptide), CAT (catalytic), MAM, TRAF, EGF-like, TM (transmembrane region), C (cytosolic). (b) Model of membrane human meprin β/β dimer based on the crystal structure of the ectodomain (Arolas *et al.*, 2012). Color code according to (a). (c) Magnification of the active site cleft of meprin β reveals several positively charged residues critical for the cleavage specificity. Cleavage site specificities of human meprin α (d) and meprin β (e) based on peptide library cleavage assays (Becker-Pauly *et al.*, 2011). Amino acids are presented in the one letter code and frequency of certain residues in prime and non-prime positions is indicated by the size. Figures were generated using icelogo.

meprin β (Hedrich *et al.*, 2010). Interestingly, fetuin-A and cystatin C belong to the cystatin superfamily of protease inhibitors, indicating a general mechanism of inhibition by this group of proteins.

In addition to endogenous inhibitors, several small compounds were identified capable of reducing meprin activity (Kruse *et al.*, 2004). Most of these molecules are hydroxamate derivatives, which exhibit strong zinc-chelating

capacity, therefore often regulating a broad range of metalloproteases. However, targeting meprins under certain pathological conditions need the development of highly specific compounds to avoid cross-reactivity with other metalloproteases, which will be future challenge in the field (Madoux *et al.*, 2014).

Cleavage Specificity and Identification of Substrates by Proteomics

Meprins display broad expression pattern in humans, including brain, skin, intestine, and kidney (Broder and Becker-Pauly, 2013). However, only few substrates have been described and little was known about the cleavage specificity until recently, when the proteomics approaches PICS (proteomic identification of cleavage site specificity) and TAILS (terminal amine isotopic labeling of substrates) were applied for meprin α and meprin β . Using PICS a strong preference for negatively charged amino acid residues in the P1' position was identified, although more prominent for meprin β than for meprin α (Becker-Pauly *et al.*, 2011; Figures 2(d) and 2(e)). This cleavage specificity was found to be unique for the astacin family and, to date, it seems to be exclusive among extracellular proteases. Interestingly, most of the substrates of meprin β contain a glutamate or aspartate in the P1' position. This striking cleavage specificity becomes even more evident as meprin β is capable of efficiently cleaving completely negatively charged sequence motifs (Broder and Becker-Pauly, 2013). The recently solved crystal structure of meprin β helps to understand this special feature. Several positively charged arginine residues within the active site cleft of meprin β perfectly interact with the negatively charged residues of the substrate leading to the striking cleavage specificity (Figure 2(c)). This unique property combined with the knowledge of the structure of meprin β might help to design highly specific inhibitors.

The application of the mass spectrometry-based proteomics approach TAILS was a step forward in meprin research. This technique enabled the identification of 151 new substrates of meprin α and meprin β , and revealed complex networks of proteolytic events in the protease web (Jefferson *et al.*, 2013). This knowledge contributes to a deeper understanding of the physiologic and pathologic role of meprin α and meprin β and might be beneficial for the development of specific drugs.

Physiologic and Pathologic Role of Meprin α and Meprin β

Meprin in Inflammation

Meprins are highly expressed in rodent kidney and represent up to 5% of total brush border membrane protein (Craig *et al.*, 1987). Therefore changes in their expression levels often lead to pathologies. The first indication for meprin's role in acute renal failure was given when mice of the strains C3H/He and CBA/Ca developed less severe forms of kidney disease after injury, compared to other mouse strains (Trachtman *et al.*, 1995). Interestingly, the mouse strains C3H/He and

CBA/Ca were shown to express meprin β , but no meprin α in proximal tubular cells (Beynon and Bond, 1983). In healthy kidney, meprin α is secreted into the lumen of the proximal tubule, while meprin β is tethered to the apical plasma membrane (Walker *et al.*, 1998). In pathological situations such as ischemia-reperfusion injury or a cisplatin-induced acute kidney injury (AKI), meprin α and meprin β undergo redistribution from apical to basolateral tubular basement membranes (Oneda *et al.*, 2008; Bylander *et al.*, 2008; Herzog *et al.*, 2007). This leads to an elevated meprin activity at the basement membrane, and consequently to tissue damage by degradation of components of the basement membrane (Walker *et al.*, 1998; Kaushal *et al.*, 1994; Kruse *et al.*, 2004; Ambort *et al.*, 2010).

The role of the metalloprotease meprin α in inflammation is further supported by the observation that the gene encoding for meprin α , MEP1A (gene encoding for human meprin α) is genetically associated with inflammatory bowel disease. SNPs (single nucleotide polymorphisms) for MEP1A were found in ulcerative colitis patients and a down-regulation for the mRNA expression of MEP1A in the epithelium has been observed during intestinal inflammation (Banerjee *et al.*, 2009; Boyd *et al.*, 2010; Coskun *et al.*, 2012). In a DSS (dextran sodium sulfate)-induced colitis model, meprin α knock-out mice express a more severe inflammation and intestinal injury compared to wild type animals, supporting the anti-inflammatory role of this metalloprotease (Banerjee and Bond, 2008). However, it remains elusive which proteolytic event is responsible for this phenotype. Several studies proposed meprins to be modulators of the immune environment by processing of pro-inflammatory cytokines such as interleukin (IL)-1 β , IL-6, IL-18, or tumor necrosis factor (TNF) α (Banerjee and Bond, 2008; Herzog *et al.*, 2009; Minder *et al.*, 2012; Keiffer and Bond, 2014). Although both meprins process IL-1 β , only meprin β has been shown to activate IL-18. According to this, in DSS-treated meprin β knock-out mice the activation of IL-18 is reduced and these animals are less susceptible to intestinal inflammation compared to wild type mice.

Alternatively, several studies demonstrated meprin α being involved in epidermal growth factor receptor (EGFR) signaling by generation of soluble transforming growth factor α (TGF α) and EGF and consequently leading to an activation of the ERK1/2 signaling cascade (Minder *et al.*, 2012; Bergin *et al.*, 2008). This results in increased cell proliferation and cell migration in response to the meprin α induced EGFR activation, indicating meprin α to be involved in the spreading of cancer cells. Further, in human bronchial epithelial cells, soluble TGF α generated by meprin α binds and activates the EGFR/TLR4 (epidermal growth factor receptor/Toll-like receptor 4) signaling cascade (Bergin *et al.*, 2008). Interestingly, the activation of the EGFR/TLR 4 signaling leads to an increased secretion of IL-8, a neutrophil chemo-attractant implicated in chronic inflammatory diseases such as cystic fibrosis (CF). Cosgrove *et al.* (2011) demonstrated an elevated expression of meprin α in mice suffering from CF, pointing to the role of this protease in inflammatory lung disease.

The role of meprin α in inflammation is supported by the observation that meprin α knock-out mice exhibit less renal damage compared to wild type mice. Additionally, meprin β deficient mice show lower levels of the inflammatory marker

IL-6 and a decreased leukocyte infiltration after renal injury (Yura *et al.*, 2009; Bylander *et al.*, 2008).

The influence of meprin α in the pathology of renal injury could be confirmed by the administration of the meprin-specific hydroxamate inhibitor actinonin (Carmago *et al.*, 2002; Takayama *et al.*, 2008). The use of actinonin in a sepsis-induced AKI mouse model led to the inhibition of the initial peritubular capillary dysfunction, as well as the subsequent tubular injury suggesting meprins as possible therapeutic targets in renal injury and sepsis (Wang *et al.*, 2010). A number of studies addressed the role of meprins as diagnostic markers, which could possibly be a target for therapeutic treatment in renal diseases (Berthier *et al.*, 2006).

Meprin in Angiogenesis and Cancer

The pro-angiogenic activity of meprin α was firstly discovered in zebrafish, where a knock-down of meprin α mRNA expression led to severe abnormalities of the vascular system (Schutte *et al.*, 2010). Zebrafish embryos failed to develop intersegmental vessels, even at the age of 48 hpf. Only the large dorsal aorta was generated, however, the blood circulation was interrupted leading to enormous developmental deficits and an early death of the embryos. This morpholino knock-down of meprin α mimics in many details the phenotype of vascular endothelial growth factor-A (VEGF-A) morphants (Nasevicius *et al.*, 2000), pointing out a general pro-angiogenic role of meprin α . Interestingly, using the proteomics technique TAILS, VEGF-A was identified as one of the substrates of meprin α . *In vitro* it has been shown that meprin α generates the same cleavage products of VEGF-A as found in wild type zebrafish (Schutte *et al.*, 2010; Jefferson *et al.*, 2013).

Further, employing TAILS identified connective tissue growth factor (CTGF), another key player in the development of blood vessels, as a substrate of meprin α (Jefferson *et al.*, 2013). During angiogenesis, CTGF forms a complex with VEGF-A, consequently immobilizing VEGF-A in the extracellular matrix (ECM) and preventing the binding of VEGF-A to its receptor. *In vitro* experiments confirmed that enzymatic cleavage of CTGF by meprin α triggers angiogenesis. This leads to a meprin α induced release of VEGF-A from the CTGF/VEGF-A complex. Soluble VEGF-A is then able to bring to its receptor and to induce angiogenesis. Interestingly, meprin α knock-out mice contain VEGF-A clusters due to the lack of the proteolytic activity of meprin α in those animals. In hens' egg chorioallantoic membrane (CAM) assay of chicken embryos meprin α showed pro-angiogenic effects by modifications of the CTGF-VEGF-A complex. While VEGF-A had no influence on the vasculature in complex with CTGF, the proteolytic processing of CTGF by meprin α significantly induced an increase in number and growth of blood vessels. By analogy, in a rat aortic ring assay, meprin α was able to promote the outgrowth, length, and branching of capillaries (Lottaz *et al.*, 2011).

The pro-angiogenic role of meprin α was further described in cardiovascular homeostasis. The metalloprotease cleaves the 32-amino acid B-type natriuretic peptide (BNP1-32) to BNP 8–32 or BNP 7–32 *in vitro* and *in vivo*, respectively, resulting in reduced natriuretic bioactivity of this protein (Boerrigter *et al.*, 2009). Thus, meprin α modulates the bioactivity of BNP 1–32

and might be a potential therapeutic target in cardiovascular diseases.

Additionally, enzymatic activity of meprin α has been found in several tumors such as breast and colon carcinoma (Lottaz *et al.*, 1999; Matters *et al.*, 2005). Although the expression of meprin α varies between different carcinomas, with quite low levels in ovarian cancer compared to gastrointestinal carcinomas (Heinzelmann-Schwarz *et al.*, 2007; Lottaz *et al.*, 2011), it contributes to the breakdown of stromal structure as it is secreted into the tumor stroma. This might lead to proteolytic modulation of ECM and consequently to the proliferation and migration of tumor cells into the surrounding tissue. In cell culture experiments it has been shown that meprin α directly promotes cell migration and treatment of human breast carcinoma cells with the specific meprin inhibitor actinonin resulting in decreased invasiveness *in vitro* (Lottaz *et al.*, 2011; Matters *et al.*, 2005). However, the pro-angiogenic effect of meprin α and its role in collagen deposition might be even more important for cancer pathology. Using proteomics for the identification of substrates it becomes more and more evident that the role of meprin α in cancer might be more complex than the ECM degrading function known for certain matrix metalloproteases (MMPs). The pro-angiogenic function of meprin α and its crucial role in collagen deposition (see section Meprin in Skin and Fibrosis) displays the relevance of this protease and its important role in drug development.

Meprin in Skin and Fibrosis

In human skin, meprin α and meprin β are constitutively expressed in the epidermis (Becker-Pauly *et al.*, 2007). While meprin α is exclusively expressed in the *Stratum basale*, where it regulates cell proliferation and migration, meprin β is only expressed in the *Stratum granulosum* where it induces terminal differentiation and might be involved in the formation of the cornified envelope. Meprins are expressed as zymogens and require the removal of their propeptides to gain proteolytic activity. Ohler *et al.* (2010) demonstrated that serine proteases KLK 4, 5, and 8 might be responsible for this activation process in skin.

Recently it became evident that meprins are involved in the assembly of collagen fibrils and in collagen deposition and are therefore important for the integrity of connective tissue. Increased collagen deposition often leads to fibrosis. Therefore, it was not surprising that meprins were found to be highly overexpressed in human fibrotic skin and in fibrotic lung tissue (Kronenberg *et al.*, 2010; Biasin *et al.*, 2014). After secretion of the collagen precursor molecule procollagen, it undergoes proteolytic modifications, which lead to the formation of collagen fibrils. Procollagen contains N- and C-terminal propeptides that have to be removed by enzymatic cleavage to allow the collagen fibril to assemble. For a long time the procollagen N-proteinase activity has been referred to a disintegrin and metalloprotease with thrombospondin motifs (ADAMTS)-2, -3, and -14, and the only known C-proteinases were bone morphogenetic protein (BMP)-1 and tolloid-like proteases (Moali and Hulmes, 2009). In contrast to other procollagen proteinases which cleave off only C- or N-propeptides, meprin α as well as meprin β are unique in the

removal of both propeptides from type I and type III procollagen, thereby inducing *de novo* fibrillogenesis (Broder *et al.*, 2013; Kronenberg *et al.*, 2010). The physiological relevance of meprin α and meprin β in collagen assembly became evident by analyzing meprin deficient mice. Due to the lack of the procollagen proteinase activity of meprins, these mice exhibit greater amounts of the unprocessed procollagen I compared to wild type mice and a significantly reduced collagen deposition in skin. This results in a markedly decreased tensile strength of the skin, reminiscent of the fragile skin of Ehlers-Danlos syndrome VII patients. This phenotype is the result of a deletion mutation in the N-proteinase cleavage site in the Col1A1 or Col1A2 genes, or alternatively, lack of ADAMTS-2 activity, both leading to the retention of the N-propeptide of type I procollagen (Colige *et al.*, 2004). Interestingly, investigation of the cleavage site generated by meprins revealed exactly the same site, which is deleted in Ehlers-Danlos syndrome VII patients (Broder *et al.*, 2013). The distinct phenotype of meprin α and meprin β knock-out mice indicates a strong physiological relevance of meprins in collagen assembly and in the maintenance of the integrity of the skin.

On the other hand, both meprin α and meprin β were found being overexpressed in the dermis of human fibrotic skin, where they might be responsible for strong collagen deposition (Kronenberg *et al.*, 2010). Additionally, micro-array studies identified meprin β as an important factor in fibrotic lungs from patients suffering from pulmonary hypertension. It was not only highly overexpressed in diseased lungs, but also the most up-regulated gene in the corresponding mouse model (Biasin *et al.*, 2014). An acute overexpression of meprin consequently leads to an increased collagen deposition in this tissue resulting in fibrosis. Thus, inhibition of meprin activity under these pathologic conditions might be beneficial for the therapeutic treatment of fibrosis.

Meprin in Neurobiology

The role of meprin β in neurobiology was not known until the amyloid precursor protein (APP) was identified as a substrate for meprin β . Using TAILS, APP was found being shed from the cell surface by the membrane-bound meprin β , releasing the soluble APP fragment (sAPP β) and the membrane-bound C-terminal 99 amino acids of APP (C99) similarly to the β -secretase BACE1 (β -site APP-cleaving enzyme 1) (Bien *et al.*, 2012). C99 is further cleaved by γ -secretase, an event that leads to the generation of a small intracellular fragment and the neurotoxic C-terminal A β peptide (Selkoe, 2001). Upon cleavage A β peptides form plaques which are thought to have a pathologic effect on the progression of the Alzheimer's disease. In general, the majority of the released A β peptides is 40–42 amino acids in length. Interestingly, the β -secretase activity of meprin β leads to the generation of different A β species as it cleaves not only at the β -secretase cleavage site but also in close proximity. Bien and colleagues (2012) demonstrated that overexpression of meprin β results in the release of N-terminally truncated A β variants. Strikingly, exactly the same A β variant is found in human cerebrospinal fluids indicating that meprin β might be responsible for this proteolytic event *in vivo* (Wiltfang *et al.*, 2001). On the other hand, the application of TAILS identified ADAM10 as a substrate for meprin β and it

was demonstrated *in vitro* and *in vivo* that meprin β activates the α -secretase (Jefferson *et al.*, 2013). ADAM10 is known to cleave APP within the A β region, resulting in the release of the soluble ectodomain sAPP α . This proteolytic event consequently prevents the formation and aggregation of neurotoxic A β peptides (Kuhn *et al.*, 2010).

Meprin β is expressed as a membrane-tethered homodimer. However, it can be shed from the cell surface by ADAM (a disintegrin and metalloprotease) proteases (Hahn *et al.*, 2003; Jefferson *et al.*, 2013). Jefferson and colleagues have shown that soluble meprin β is able to process the N-terminus of APP *in vitro* and *in vivo* releasing N-terminal fragments of 11 and 22 kDa (APP11 and APP22) (Jefferson *et al.*, 2011). The latter was previously found in human brain lysates (Portelius *et al.*, 2010), once again suggesting the physiologic relevance of meprin β in neurobiology.

TAILS enabled the discovery of a proteolytic web of meprin β in a pathological context and to decipher meprin β 's role in neurodegeneration. Although the exact mechanism behind the generation of A β peptides remains elusive, it is unambiguous that meprin β is involved in the modulation of APP *in vivo* and might therefore be a novel therapeutic target in Alzheimer's disease.

Conclusion

Meprin metalloproteases exhibit distinctive structural and functional features. Revealing the unique cleavage specificity of these proteases with strong preference for negatively charged amino acid residues in combination with degradomic approaches enabled the identification of novel substrates important for health and disease. For instance, meprin α is a pro-angiogenic enzyme and important for certain tumor progression. Meprin β cleaves the APP at distinct sites, thereby releasing A β , a hallmark in the development of Alzheimer's disease. Both meprin α and meprin β are important for collagen fibrillogenesis, which correlates with increased meprin expression in fibrotic conditions such as keloids or pulmonary hypertension. Hence, regulation of these metalloproteases may be a suitable strategy for the treatment of associated pathological conditions.

Glossary

Angiogenesis The process of the development of new blood vessels. Angiogenesis is considered critical for tumor growth.

Extracellular matrix Refers to a substance consisting of proteins, glycoproteins, and polysaccharide that provide support as a structural scaffold for cells and can be a barrier between tissues.

Insulin-like growth factor-1 Originally known as somatomedin C and is a member of a group of proteins with homology to insulin. Insulin-like growth factor-1 is important for normal growth and is also involved in cancer cell development. Insulin-like growth factor-1 binds to an insulin-like growth factor binding protein where it is inactive; degradation of insulin-like growth factor binding protein results in the release of active insulin-like growth factor-1.

Kinin A biologically active peptide derived from precursor proteins, kininogens. Kinins are best known for vasodilation

and for the contraction of smooth muscle. Recent work has suggested that kinins have more diverse activities.

Missense polymorphism A mutation in DNA which results in a change in the amino acid sequence of proteins. A missense polymorphism results from the change in a single base in a codon; the change from CGC which codes for arginine to CAC (substitution of adenine to guanine) results in histidine in place of arginine in the amino acid sequence of the expressed protein.

Nitric oxide Originally described as endothelium derived relaxing factor (EDRF) which caused smooth muscle relaxation. Nitric oxide can react with peroxide to form peroxynitrite which has a variety of biological functions.

Pleiotropic Describing the ability of an object to have multiple functions.

Urokinase A plasminogen activator originally isolated from urine. Now known as urokinase-type plasminogen activator or urokinase plasminogen activator.

Introduction

Proteases can be separated into two groups: digestive proteases and regulatory proteases (Neurath, 1985). Trypsin and chymotrypsin are examples of digestive proteases while the coagulation enzymes and complement proteases are considered to be of the regulatory type. Thirty years ago, plasma kallikrein (KLK) and tissue/glandular KLK were two regulatory proteases defined by their ability to liberate kinins from kininogens. There was emerging evidence to suggest a role for KLK activity in processing growth factor precursors (Blabber *et al.*, 1989) and prostate-specific antigen (PSA) was a KLK-related protein identified early on as a biomarker for prostate cancer (Wang *et al.*, 1981). The past 20 years has seen a dramatic increase in the number of KLK-related peptidases identified (Table 1).

Plasma KLK

KLK is a functional activity defined by the cleavage kininogens to form kinins, which are vasoactive peptides (Schachter, 1979). Plasma KLK and tissue (glandular) KLK differ in distribution, size, and specificity. Plasma KLK has a molecular weight of 80–90 kDa depending on the extent of glycosylation (Björkqvist *et al.*, 2013) while tissue KLK has a molecular weight of approximately 40 kDa (Pathak *et al.*, 2013). Both are synthesized in precursor or zymogen form; prekallikrein (preKLK) in the case of plasma KLK and prokallikrein (proKLK) in the case of tissue KLK. The plasma moiety liberates kinin activity from high-molecular weight kininogen (HMWK) while tissue KLK

releases kinin activity from either HMWK or low-molecular weight kininogen (LMWK). Plasma preKLK is thought to participate in the contact phase of blood coagulation and it has been shown to circulate as a complex with HMWK (Saito and Ratnoff, 1979). HMWK, which has been cleaved by plasma KLK to a two-chain protein, HMWk_a, inhibits angiogenesis (Tesfay *et al.*, 2012). The activation of preKLK in plasma involves factor XIIIa, HMWK, endothelial cell surface, including proteoglycans, and prolylcarboxypeptidase. A sequential series of proteolytic events, occurring as a cascade, has been proposed for the KLK/bradykinin system (Figure 1; Kaplan and Joseph, 2010).

Tissue KLK

Tissue KLK (also KLK1) is a secretory product of the salivary glands and the pancreas and is found in the kidney. As with plasma preKLK, tissue KLK is synthesized as a zymogen, which is activated by limited proteolysis. Classic tissue kallikrein (KLK1) may be partially activated during the secretory process (Jenzano *et al.*, 1988; Peters *et al.*, 1992). Several proteases have been shown to activate proKLK, including trypsin, thermolysin, and clostripain but a physiological activator has not been identified (Mauer and Kemme, 2002). The failure to detect significant active KLK1 in the various biological fluids is likely a consequence of reaction with various inhibitors including α_2 -2-macroglobulin and α_1 -antitrypsin (Shimamoto *et al.*, 1984; Rahman *et al.*, 1994). Kallistatin was identified as a specific serpin inhibitor of tissue KLK (Chao *et al.*, 1996). Kallistatin has also been shown to have a negative effect on

Table 1 KLK-related peptidases

<i>KLK-related peptidase</i>	<i>Other names and tissue source</i>	<i>References</i>
KLK1	Classical tissue KLK or glandular KLK; primary sites of synthesis in pancreas, kidney, and salivary glands; wide tissue distribution	Chao (2013)
KLK2	Human glandular kallikrein 1; exclusive in the prostate	Veneris-Lowe <i>et al.</i> (2007)
KLK3	Prostate-specific antigen; exclusive in prostate	Mattsson <i>et al.</i> (2008)
KLK4	Protease; wide distribution including prostate and enamel; expressed in ovarian cancer	Stephenson <i>et al.</i> (1999)
KLK5	Human stratum corneum tryptic enzyme (SCTE); found in skin and breast tissue; ovarian cancer	Yousef <i>et al.</i> (2003)
KLK6	Protease M; found in brain, pancreas; proposed a biomarker for ovarian cancer, brain trauma	Bayés <i>et al.</i> (2004)
KLK7	Human stratum corneum chymotryptic enzyme (SCCE); found in skin, esophagus, heart, pancreas	Ramani <i>et al.</i> (2011)
KLK8	Neuropsin; found in brain, skin, and breast	Kishi <i>et al.</i> (2003)
KLK9	Wide tissue distribution; ovarian tumors, breast tumors	Memari <i>et al.</i> (2006)
KLK10	Normal epithelial cell-specific 1; NES1 serine protease; wide tissue distribution	Liu <i>et al.</i> (1996)
KLK11	Hippostasin, trypsin-like serine protease; TLSP; wide tissue distribution with various isoforms	Yoshida <i>et al.</i> (1998)
KLK12	KLK-like 5; first identified by sequence analysis of the chromosomal region encoding other members of the kallikrein-related peptidase family; it is suggested to have isoforms showing a wide tissue distribution	Yousef <i>et al.</i> (2000b)
KLK13	KLK-L4	Petraki <i>et al.</i> (2003)
KLK14	Wide tissue distribution	Yousef <i>et al.</i> (2000a)
KLK15	Prostin; prostinogen; ACO protease, hK15; found in prostate, colon, thyroid	Batra and Clements (2013)
Plasma KLK	Formed from plasma prekKLK (Fletcher factor), synthesized in liver and found in liver and interstitial fluid)	Schmaier and McCrae (2007)

Note: This table is a listing of human kallikrein-related peptidases. The rat and mouse KLK families are somewhat more complex (see Lundwall *et al.*, 2006)

wound healing through inhibition of Wnt/ β -catenin signaling pathway (McBride *et al.*, 2014).

Tissue KLK is suggested to have both kinin-dependent (Zaika *et al.*, 2011) and kinin-independent (Chambrey and Picard, 2011) functions in the kidney. Tissue KLK is not constitutively expressed in the kidney (Cumming *et al.*, 1994). Use of AAV (adeno-associated virus)-mediated gene therapy with human tissue KLK has been shown to protect renal function in acute renal failure in rats (Tu *et al.*, 2008). Urine has been a source for the purification of tissue KLK (Girolami *et al.*, 1989) and tissue proKLK (Takada *et al.*, 1985).

Tissue KLK is also expressed in pancreatic secretions and in saliva and its mRNA has also been shown to be present in heart tissue in rats (Campbell *et al.*, 2011). There are several variants of tissue KLK (Chan *et al.*, 1998; Fiedler *et al.*, 1999). A missense polymorphism, which results in the insertion of a histidine for arginine at position 53 in human tissue (urinary) KLK (R53H) is associated with the loss of kinin-generating activity (Slim *et al.*, 2002). The crystal structure of urinary KLK1 suggested that Arg53 is critical for the binding of substrate. Subsequent work (Azizi *et al.*, 2005) showed this mutation was associated with arterial dysfunction. More recent work with a murine model system indicated that tissue KLK is critical for arterial repair. Kinin-B2 receptor interaction by tissue KLK and the activation of MMP-9 are important for increased angiogenesis (Stone *et al.*, 2009).

Kinins

Much of the physiological action of plasma KLK and tissue KLK is mediated through the production of biologically active

peptides known as kinins (Roche e Silva *et al.*, 1949; Schachter and Thain, 1954). Bradykinin is produced by plasma KLK acting on HMWK while lysylbradykinin (kallidin) is produced by tissue KLK from either HMWK or LMWK. Lysylbradykinin can be converted to bradykinin through the action of an aminopeptidase. Kinins were originally described as vasoactive peptides, which lower blood pressure and cause uterine and intestinal contractions in an action mediated by nitric oxide (Moncada *et al.*, 1988). It is now apparent that kinins are pleiotropic (Maurer *et al.*, 2011) and they are of importance in cancer (da Costa *et al.*, 2014).

Kallikrein-Related Peptidases

The KLK family is comprised of 15 proteins (Harvey *et al.*, 2000; Lundwall *et al.*, 2006; Table 1). The majority of these have activity unrelated to the classic definition of a KLK as a kininogenase (Kraut *et al.*, 1930). The KLK-related peptidases function as secretory factors in the extracellular space where they have diverse functions including the processing of growth factors, cleavage of extracellular matrix proteins, and activation of other proteases. They are also involved in tumorigenesis (Dong *et al.*, 2014).

KLK2 and KLK3 (PSA) are exclusive products of the prostate and have been used for prostate cancer screening (Lövgren *et al.*, 1995; Voigt *et al.*, 2014). KLK-related peptidase 2 (KLK2, hK2) has been shown to have kininogenase activity (Deperthes *et al.*, 1997; Charlesworth *et al.*, 1999) while PSA has little (Andrade *et al.*, 2010) or no kininogenase activity (Deperthes

Figure 1 Cascade systems for the expression of kallikrein-like peptidase activity. (a) A putative scheme for the interaction of contact activation (Factor XII) and plasma prekallikrein to form kallikrein which can then activate pro-urokinase to form urokinase and form bradykinin from HMWK (Kaplan and Ghebrehiwet, 2010). (b) A putative scheme by which KLK1 could initiate a cascade of KLK peptidases resulting in formation of KLK14 which would degrade collagen type IV thus permitting tumor metastasis, would degrade IGF-BP with the liberation of IGF which would foster tumor cell growth, and cleave PAR-2 receptor also stimulating tumor cell growth (Gratio *et al.*, 2011; Albrechtsen *et al.*, 2013). KLK14 may also form biologically active peptides from complement C3 (Oikonomopoulou *et al.*, 2013). (c) An example of the interaction of the thrombostasis proteases with the KLK peptidases where thrombin activates proKLK12 resulting in the sequential activation of proKLK11 and proKLK14 (Blaber *et al.*, 2010; Guillon-Munos *et al.*, 2011; Kryza *et al.*, 2014). (d) A KLK cascade initiated by a matrix metalloproteinase which had been activated by urokinase. Urokinase activates pro-MMP12 which then activates proKLK4 which then activates proKLK11 (Debela *et al.*, 2008; Ohler *et al.*, 2010). This cascade has the potential to degrade extracellular matrix (MMP-3), activate PAR-1 receptors on various target cells including tumor cells (Wang *et al.*, 2010).

et al., 1997). Both KLK2 and PSA are considered primary secretory products of the prostate and, as with other KLK-related peptidases, they are products derived by alternative splicing (David *et al.*, 2002).

KLK-related peptidases which include tissue kallikrein (Table 1) have been shown to be present in a large number of tissues and fluids by mRNA analysis and highly sensitive immunoassays (Shaw and Diamandis, 2007). The presence of

Table 2 Cell receptor targets for KLK-related peptidases

<i>KLK-related peptidase</i>	<i>Cell receptor targets</i>	<i>References</i>
KLK1	PAR-1 on several cell types; suggested transactivation of EGF receptor	Gao <i>et al.</i> (2010), Oikonomopoulou <i>et al.</i> (2006), Lu <i>et al.</i> (2014)
KLK4	PAR-1 on colon cancer cells	Gratio <i>et al.</i> (2010)
KLK5	PAR-2 on keratinocytes	Stefansson <i>et al.</i> (2008)
KLK6	PAR-1 and PAR-2 on neurons	Yoo <i>et al.</i> (2013)
KLK8	Cannot activate PAR-2 but does inactivate PAR-1 in human embryonic kidney (HEK) cells; can activate Kristen transformed rat kidney (KTRK) cells expressing PAR-2	Ramachandran <i>et al.</i> (2012)
KLK14	KLK14 can cleave PAR-2 on HEK cells and in KTRK cells. KLK14 was able to activate PAR-2 in colon cancer cells	Gratio <i>et al.</i> (2011)
Plasma KLK	Cleavage of PAR-1/PAR-2 in vascular smooth muscle cells results in transactivation of the EGF receptor	Abdullah <i>et al.</i> (2010)

KLK-related peptidases 5, 6, 7, 10, 11, 12, 13, and 14 in the cytoplasm of glandular epithelial cells and in cellular secretions has been established with immunohistochemistry (Petraki *et al.*, 2006).

There are several substrates of KLKs that are notable. Proteolysis of insulin-like growth factor binding protein (IGF-BP) by several members of the KLK family (Figure 1) results in increased unbound insulin-related growth factor-1 (IGF-1) in the interstitial space; increased IGF-1 is known to enhance tumor growth (Hekim *et al.*, 2010). Various other proteins have been suggested to serve as substrates for the several KLK-like peptidases (Borgono *et al.*, 2007; Debela *et al.*, 2008; Sotiropoulou and Pampalakis, 2010).

The relationship between various KLKs and other proteases does suggest that functional cascades exist (Figure 1), such as observed with complement and coagulation proteases and that these are important regulatory processes (Blaber *et al.*, 2010). These processes not only involve zymogen activation but also interactions with various cells mediated by protease-activated receptors (PARs). These putative cascades involve the stepwise interaction of proteases where the zymogen form of one enzyme is converted to the activated form by limited proteolysis. Once activated, this protease can activate the next zymogen. Unlike the coagulation cascades where there is an amplification of the initiation signal, it is suggested that the kallikrein cascades are regulatory in nature and likely provide temporal control of events such as tissue remodeling.

KLK–Cell Interactions

There has been limited work on the interaction of KLK with cells (Table 2). Many of the KLK family members have a specificity for peptide bond cleavage, which would result in activation of PARs. PARs have tethered ligands where limited proteolysis in the amino terminal domain of the extracellular peptide chain results in an interaction with the G-protein coupled receptor region (Vu *et al.*, 1991; Gieseler *et al.*, 2013). There are examples of KLK-mediated transactivation of epidermal growth factor (EGF) receptors via PAR-2 cleavage (Michel *et al.*, 2014). In some cases, KLK-related peptidases can

inactivate or disarm a PAR when proteolysis occurs downstream of the activation-related scissile peptide bond (Dulon *et al.*, 2003). This would appear to be the case for KLK8, which has been shown to disarm PAR-1 on human embryonic kidney cells (HEK cells) (Ramachandran *et al.*, 2012). KLK8 was able to activate PAR-2 receptors in a transformed rat kidney cell line. KLK14 has been shown to activate PAR-2 receptors in a human colon cancer cells line and it is suggested that there is ectopic expression of KLK14 in colon cancer cells (Gratio *et al.*, 2011) inducing Erk1/Erk2 expression. The ectopic expression of KLK14 in colon cancer cells and PAR-2 activation would provide an autocrine pathway for cancer cell proliferation.

KLK and Cancer

An association of KLK with cancer has been suggested for some time dating at least to an observation on kinin release in carcinoid syndrome (Oates *et al.*, 1964). The use of KLK2 and KLK3 as biomarkers for prostate cancer is well known; there is evaluation of other KLK-like peptidases as biomarkers in other malignancies (Kashuba *et al.*, 2013; Dorn *et al.*, 2013; Vakrakou *et al.*, 2014). More recently, aprotinin has been shown to inhibit tumor growth, possibly on the basis of inhibition of KLKs (Vaporciyan *et al.*, 2004). KLK-like peptidases have a broad range of biological activities which would be useful in tumor growth and metastasis. The fragmentation of IGF-BP-3 by several members of the KLK family results in the increase of IGF activity fostering tumor growth. Tumor metastasis may be influenced directly by the proteolysis of collagen type IV by KLK-related peptidases or by the activation of other protease systems such as the matrix metalloproteinases (Pezzato *et al.*, 2004). There is considerable interest in the relationship of IGF-1 and KLK3 in prostate cancer (Holmberg and Van Hemelrijck, 2014). While there is no data to support a direct effect, KLK3 will activate KLK14, which can degrade IGF-BP.

Glossary

Apollon The human homolog of *Drosophila* BRUCE, a high molecular weight inhibitor of apoptosis (IAP), also known as BIRC6 protein.

Apoptosome A multimeric protein complex that mediates the activation of a caspase that initiates apoptosis; the human complex includes cytochrome c, Apaf-1 (apoptotic protease activating protein-1) and deoxy-ATP.

Cathelicidins A family of antimicrobial peptides found in the secondary granules of neutrophils and in some other cells.

Cathepsins A family of cysteine proteases related to papain, members of family C1 in the MEROPS database of proteolytic enzymes.

Fetuin (α 2-HS-glycoprotein) A multifunctional cystatin found in serum.

Inflammasome A multi-protein complex containing NOD-like receptors that promote the proteolytic activation of pro-inflammatory cytokines, IL1 β and IL18.

Latexin A mammalian inhibitor of metallocarboxypeptidases A, a member of MEROPS inhibitor family I47, clan IH.

Neddylation The process of covalent coupling of proteins with the ubiquitin-like protein, NEDD8.

Proteasome A large protein complex that degrades ubiquitin-tagged proteins in the cytoplasm and nucleus.

Serinopathy A disease caused by a misfolded serpin.

Survivin An IAP and regulator of mitosis, expressed in tumors and fetal cells, also known as BIRC5.

Tazarotene A retinoid pro-drug that is de-esterified to form tazarotenic acid, which binds to members of the retinoic acid receptor (RAR) family; used in treatments for acne and psoriasis.

Thrombophilia A disorder in which there is an increased tendency to form blood clots.

Ubiquitination The covalent coupling of proteins with ubiquitin.

General Introduction

Proteases catalyze peptide bond hydrolysis, a reaction underlying protein digestion and turnover. However, most proteases have restricted specificities reflecting roles in specific physiological processes, for example, the release of biologically active peptides from larger protein precursors, the activation of proenzymes and receptors, removal of localization signals, or cell signaling. In these processes, protease activity is needed for a limited duration, requiring the regulated production of active proteases through transcription, localization and zymogen activation and termination by endogenous inhibitors, structural change or degradation. Protease inhibition, which generally involves the action of specific protein inhibitors, is essential for avoiding the potentially pathogenic effects of unregulated proteolysis. Typically, the production of protein inhibitors accompanies the production of their cognate proteases; however, some pathogens produce inhibitors of specific proteases made by their hosts.

Polypeptide protease inhibitors vary in specificity, structure, and mechanism of action. Homologous inhibitors tend to target a particular class of protease, but that is not universal. Some families include members with diverse functions that inhibit different protease classes or lack inhibitory activity. This article focuses on some key families of protease inhibitors that vary in origins, chemistry, and biology. This article is not comprehensive; omissions include canonical inhibitors of serine proteases (e.g., pancreatic trypsin inhibitor), α ₂-macroglobulin, and an array of bacterial, yeast, and invertebrate inhibitors. Also, the inhibition of two medically important proteases: angiotensin I

converting enzyme (ACE) or HIV protease is not discussed because they lack protein inhibitors. A more comprehensive and detailed account of protease inhibitors is provided in MEROPS database (see 'Relevant Website' section).

Cystatins/Stefins

The cystatins (CSTs) are high affinity, reversible inhibitors of cysteine proteases including plant proteases related to papain and mammalian cathepsins. They are found in eukaryotes (animals, protozoa, plants, and algae) and bacteria, but not in archaea. CSTs fall into three groups; type 1: intracellular proteins (stefins A and B) that have about 100 residues and lack disulfide bonds and a secretion signal peptide; type 2: secreted CSTs (C, D, E, F, S, SA, and SN) with about 120 amino acids that have two conserved disulfide crosslinks and a secretion signal sequence; type 3: kininogens which are multidomain proteins containing three type-2 CST domains of which one is inactive as a protease inhibitor. CST domains are also present in other proteins that do not function as protease inhibitors including fetuin-A (histidine-rich glycoprotein or HRG). CSTs S, SA, and SN are closely similar in sequence (90% identical). Molecular phylogeny studies indicate that the CSTs originated in an ancestor of the eukaryotes from an intracellular form; a gene duplication subsequently generated two lineages: stefins (type 1) and CSTs (types 2 and 3). The CST line has diverged functionally and structurally during the evolution of multicellular eukaryotes through multiple domain and gene duplications (Kordiš and Turk, 2009).

Structure and Inhibition Mechanism

The structures of a number of type 1 and type 2 CSTs have been determined including human CSTs A, B, C, D, and F, chicken, tick, and plant CSTs, together with CST-protease complexes. Their shared CST fold consists of a 5-stranded antiparallel β -sheet that is wrapped around a 5-turn α -helix (Figure 1). CSTs inhibit cysteine proteases by blocking the active site; the regions that interact with the protease are the N-terminus and two loops connecting the second and third and fourth and fifth β -strands. This forms a wedge-like structure that inserts into the active site but does not interact with the catalytic cysteine (see Figure 1).

Tissue Distribution

Stefin A (type 1 CST) has a restricted tissue distribution, being found mainly in epidermal cells whereas stefin B is expressed in a wide range of cells. Among the type 2 CSTs, C is widely distributed in different tissues while D, S, SA, and SN are largely found in glandular tissues. CST F is targeted to endosomes and lysosomes and is selectively expressed in immune cells. CST 8 (CRES, CST-related epididymal spermatogenic protein), 9 (testatin), 11 and 12 (CST T) are localized in the male reproductive tract, while CST13 (CLM, cystatin-like

molecule) is in bone marrow and CST14 is a secreted phosphoprotein, also known as ssp24.

Biological Functions

The stefins (Type 1 CSTs) retain the intracellular cysteine protease inhibitory function of the CST ancestor, while proteins encoded by the lineage leading to type 2 and 3 CSTs acquired a secretion signal sequence and disulfide bonds, expanding through multiple gene duplications to produce proteins with diverse extracellular functions. Type 1 and 2 CSTs inhibit papain-like proteases and the lysosomal cysteine proteases, including cathepsins B, L, H, and S, but with varying affinities. Some type 2 CSTs are found in body fluids, including saliva and tears (S, SA, and SN). CRES (CST8) has been reported to inhibit the serine protease, prohormone convertase and is important for fertility of spermatozoa.

Type 3 CSTs are more variable in structure and function. Fetuin-A (histidine-rich glycoprotein, HRG) in plasma and platelets binds heparin. CST14 is an abundant serum phosphoprotein that binds cytokines of the bone morphogenetic protein/transforming growth factor- β (BMP/TGF β) superfamily. Cathelicidin has a variable C-terminal antimicrobial domain attached to a conserved CST region. Processing by skin proteases enables the antimicrobial activity. Tazarotene-induced gene 1 (TIG1) is known to function as a cell adhesion molecule, which leads to better cell–cell contacts and reduced proliferation of target cells. Latexin inhibits Zn²⁺-carboxypeptidase A4 in mammals and may be involved in the homeostasis of hematopoietic stem cells. Kininogen contains three type 2 CST domains, in tandem, of which two inhibit cysteine proteases in the circulation (lysosomal and microbial). Its cleavage by plasma kallikrein releases bradykinin, which reduces blood pressure through vasodilation.

CSTs and Disease

Mutations in stefin B, resulting from expansion of a nucleotide repeat, cause myoclonic epilepsy of Unverricht and Lundborg (EPM1), an autosomal recessive disorder that results in neurodegeneration at 6–13 years of age. The disease progresses during adolescence but tends to stabilize in adulthood. Two different mutations in CST C have been linked to diseases. A Leu68 to Gln mutation causes cerebral ‘icelandic-type’ amyloidosis, accompanied by intracerebral hemorrhage in the elderly (Ghiso *et al.*, 1986) while the Ala25 to Thr mutation causes a form of age-related macular degeneration (AMD). The latter appears to result from intracellular mislocalization to mitochondria (Zurdel *et al.*, 2002). Mutations in HRG resulting from missense mutations can result in low circulating levels, arising from reduced secretion and a thrombophilia. Paradoxically, elevated levels of HRG is also linked to an increased risk of thrombosis (OMIM 613116).

Inhibitors of Apoptosis

Inhibitors of apoptosis (IAPs) are a family of highly conserved proteins, initially discovered in baculovirus, that are now known to include representatives in both vertebrates and

Figure 1 Ribbon structure of the complex of stefin A (green) with cathepsin H (orange). The N- and C-terminal residues of each protein are labeled as well as two loops (L1, L2) of stefin A that, together with the N-terminal region, form most of the interaction interface with the protease (Jenko *et al.*, 2003). The image was generated from chains A and I of PDB 1NB5 using Chimera (Pettersen *et al.*, 2004).

invertebrates. The IAPs were initially categorized as caspase inhibitors that prevented apoptosis in insect cells, thereby allowing the baculovirus to persist (Crook *et al.*, 1993). Subsequently, it was found that IAPs mediate other cell-signaling processes that are independent of apoptosis. These activities include regulation of inflammatory responses and innate immune signaling, the control of cell motility/migration, invasion, metastasis, and differentiation. In humans, there are eight members of the IAP family: cellular IAP1 (c-IAP1/BIRC2), cellular IAP2 (c-IAP2/BIRC3), X-chromosome linked IAP (X-IAP/BIRC4), neuronal inhibitor apoptosis protein (NIAP/BIRC1), Survivin (TIAP/BIRC5), Apollon (BRUCE/BIRC6), melanoma IAP (ML-IAP/BIRC7), and IAP-like protein 2 (ILP-2/BIRC8). Interestingly, only four are direct regulators of apoptosis (c-IAP, c-IAP2, X-IAP, and ML-IAP), while the other proteins have more indirect, if any, effects on this process (Berthelet and Dubrez, 2013).

Structure

IAPs range in size from 142 amino acids (Survivin) to 4858 amino acids (Apollon). The defining feature of an IAP family member is the presence of at least one baculovirus IAP repeat (BIR) domain near the N-terminus (Figure 2). This zinc-binding domain is comprised of 70–80 amino acids containing a conserved cysteine and histidine motif that mediates protein-protein interactions. The BIR domain has an α/β fold;

Figure 2 The structure of XIAP_HUMAN BIR2 Domain Chain A PDB 4J3Y. Secondary structure elements are displayed as ribbons and the side chains of three Zn-binding cysteines and one histidine are also shown in purple and the Zn^{2+} ion is a purple sphere. The image was rendered using Chimera (Pettersen *et al.*, 2004).

when more than one BIR is present, the domains are arranged in tandem. Type-II BIR domains have a hydrophobic groove that binds a conserved four amino acid protein motif called the IAP binding motif (IBM) found in some processed/activated caspases and IAP antagonists. Type I BIR domains act on proteins mainly involved in cell-signaling pathways in an IBM-independent manner.

In addition to the signature BIR domain, five mammalian IAPs (c-IAP1, c-IAP2, X-IAP, ILP-2, and ML-IAP) contain a C-terminal RING (really interesting new gene) domain. This zinc finger-like domain confers E3 ubiquitin-ligase activity, which facilitates ubiquitination of targets with varying effects. Finally some members of the IAP family share a caspase recruitment domain (CARD) and/or ubiquitin-associated domain (UBA) that mediate the enlistment of caspases or binding to ubiquitin moieties, respectively.

Biological Functions

IAPs are many and varied; some are multifunctional, whereas others have limited roles. The effects of IAPs on numerous pathways elicit responses that include cell death, inflammation, cell migration, cell division, and development.

Inhibition of apoptosis

Programmed cell death is a key mechanism for terminating cells under conditions of stress or at key points during development. There are two mechanisms (intrinsic and extrinsic) for initiating apoptosis. Activation of the intrinsic pathway involves the release of mitochondrial pro-apoptotic molecules (such as cytochrome *c* and second mitochondria-derived activator of caspases – SMAC/DIABLO) in response to stimuli such as free radicals, radiation or viral infections. Cytochrome *c* then initiates formation of an apoptosome, typically followed by activation of caspase 9. The SMAC protein acts by neutralizing IAPs. Conversely, the extrinsic pathway is activated by the binding of specific ligands to cell surface ‘death’ receptors of the tumor necrosis factor receptor (TNFR) family, followed by the activation of an initiator caspase (primarily caspases 8 or 10). In either mechanism, the signaling pathways rely on the serial activation of initiator followed by effector caspases (such as 3, 6, and 7). The effector caspases subsequently facilitate apoptosis. Of the human IAPs, X-IAP, ML-IAP, c-IAP1, and c-IAP2 can bind to caspases -3, -7, and -9 via their BIR domains. Their RING domains then allow for ubiquitination (or neddylation) of caspases. Interestingly, only X-IAP is able to act to directly inhibit caspases -3 and -7, by blocking the substrate binding sites, as well as -9, by preventing homo-dimerization (Berthelet and Dubrez, 2013). Other IAPs such as survivin and NIAP also have roles in apoptosis but their primary functions may be in other pathways. ILP2 protein (a tissue-specific homolog of X-IAP) is unstable and has not yet been shown to inhibit apoptosis under physiologically relevant conditions.

Regulation of inflammation and immunity

X-IAP, c-IAP1, and c-IAP2 function in the initial immune responses to tissue injury or infection, principally through their ubiquitin-ligase activity. Inflammation is initiated by the

binding of innate immune pattern recognition receptors (PRRs) to stress signals such as microbial components (pathogen-associated molecular patterns – PAMPs) or endogenous molecules released by dying cells (danger/damage-associated molecular patterns – DAMPs). Key PPRs include Nod-like receptor (NLR), Toll-like Receptor (TLR), TNFR1, and RIG-1-like receptor (RLR). The outcome of the activation of certain PPRs is initiation of the mitogen-activated protein kinase (MAPK) and/or the traditional and alternate nuclear factor- κ B (NF- κ B) signaling pathways in which the IAPs are key effectors (Estornes and Bertrand, 2014). The downstream effect of activating these pathways is often the upregulation of genes for mediators of inflammation and immunity, such as cytokines. However, the c-IAPs, under appropriate signaling can also repress one of the NF- κ B pathways. IAPs can also impact the innate immune system through NIAP, c-IAP1, and c-IAP2 control of the inflammasome (a caspase 1 activating multi-protein molecular platform). This complex is ultimately responsible for producing and secreting interleukin 1 (IL-1). c-IAP1 and c-IAP2 also affect the adaptive immune response through their regulation of TNF superfamily signaling. Both proteins are negative regulators of B lymphocyte proliferation and survival through the NF- κ B alternate pathway (Beug *et al.*, 2012).

Regulation of cell migration, invasion, metastasis, and development

The activation of the NF- κ B and/or MAP Kinase signaling pathways, that involve IAPs, affect other cellular activities besides immune responses. In higher eukaryotes, it appears that the IAPs can be positive or negative effectors of migration, invasion and metastasis, or both, under varying circumstances (Kenneth and Duckett, 2012). For example, some data suggest that the c-IAPs, upon activation of the traditional (canonical) arm of the NF- κ B pathway, can ultimately lead to an increase in interleukin-8, which will then promote migration. Conversely, other evidence suggests that c-IAP signaling in the alternate (noncanonical) arm of the NF- κ B pathway can have a negative effect on these phenotypes (Fulda, 2014). In addition to these actions of IAPs, X-IAP, and c-IAP1 are known to interact directly with the Rho GTPases that are the molecular switches modulating the dynamics of the cytoskeleton. These proteins cycle between the active (GTP-bound) form and the inactive (GDP-bound form) and interact with downstream effectors that can exert either positive or negative effects on cell movement. In colorectal carcinoma cells, data from one study suggest that X-IAP has a positive effect on actin polymerization and cell motility whereas in HeLa cells, it appears that c-IAP1 and X-IAP can limit cell migration by targeting regulators of the actin cytoskeleton for proteasomal degradation (Kenneth and Duckett, 2012).

Appropriate cell movement and apoptosis are crucial for development in higher eukaryotes. Since IAPs modulate these developmental processes, their activity during embryogenesis is vital. Studies with model organisms, including *Drosophila* and *Xenopus*, show that disruption of various IAP genes can lead to embryonic death or incorrect cell migration leading to ventralized embryos (Kenneth and Duckett, 2012). With regard to mammals, experiments in mice have shown that knockouts of either X-IAP, c-IAP1, or c-IAP2 permit relatively

normal development. However, X-IAP/c-IAP1 or c-IAP1/c-IAP2 double knockouts do not survive past day 10 of development. This suggests that the activities of these proteins may overlap, allowing mutual compensation during embryonic development.

IAPs involved in cell division and cytokinesis

The smallest (Survivin) and largest (Apollon) of the IAP proteins are implicated in cell division and cytokinesis, respectively. Survivin transcription has been shown to increase during the G2 to mitosis transition in the cell cycle. As a subunit of the chromosome passenger complex (CPC), Survivin acts by targeting the CPC to the inner centromeres (Jeyaprakash *et al.*, 2007). The presence of the CPC generates a spindle checkpoint signal that prevents the onset of anaphase until all spindle fibers are appropriately attached to the centromeres. At a later point in the cell cycle, it is thought that Apollon may interact with Survivin at the end stages of cytokinesis. Recently it has also been shown that Apollon is a novel regulator of mitotic Cyclin A protein degradation in early mitosis (Kikuchi *et al.*, 2014).

IAPs in Disease

There is considerable evidence that IAP proteins play a role in human cancers. Increased expression of certain IAP proteins (particularly X-IAP, c-IAP1, and c-IAP2) in tumors results in a worse prognosis but in other kinds of cancers, increases in IAPs can lead to a more positive prognosis. In addition, Survivin and ML-IAP (which are usually at undetectable levels in normal adult cells) are highly expressed in most tumors and specifically in melanomas, respectively. These and other studies, suggest that the IAP proteins may represent promising targets for cancer researchers. Because certain IAP proteins prevent cell death, inhibitors of these proteins may facilitate apoptosis producing a more effective treatment and improved prognosis. Currently several small molecule inhibitors of IAPs, that are SMAC mimics, are being tested as potential therapeutic tools for cancer (Dubrez *et al.*, 2013).

Serpins

Members of this ubiquitous family are found in eukaryotes, bacteria, archaea and viruses. The acronym 'SERPIN' (serine protease inhibitors) reflects the functions of the first characterized members of the family as specific inhibitors of serine proteases. There are 36 genes for serpins in humans and 60 in mice; while most function as serine protease inhibitors, some inhibit cysteine proteases (caspases and papain-like cysteine proteases) and others have a broad array of functions, including molecular chaperone activity, DNA binding, or hormone transport (Heit *et al.*, 2013). Serpins are classified in family I4 of the MEROPS database; two major divisions of the serpins are the extracellular and intracellular groups (clades A and B, respectively). The inhibitory serpins inactivate their target proteases through an unusual 'suicide' mechanism that exploits the acyl-enzyme intermediate formed during covalent catalysis by serine and cysteine proteases.

Structure

Compared with other protease inhibitors, serpins are relatively large molecules, containing 330 to 500 residues. Their structures, exemplified by the well-studied α_1 protease inhibitor (α_1 PI) have been described as containing two domains, an N-terminal α -helical domain and a C-terminal β -barrel domain. Two key structural features are a mixed (part antiparallel and part antiparallel) β -sheet, designated β -sheet A, that runs between the two domains, and a loop that extends from the β -barrel domain, that is named the reactive center loop (RCL) (Figure 3(a)). Mixed β -sheets like the A sheet are less common in proteins because the H-bonding arrangements in antiparallel and parallel β -sheets require different positioning of peptide groups.

Mechanism of Inhibition

Serine proteases

The inhibitory mechanism of α_1 PI (and some other serpins, including antithrombin III (AT)) has been established by structural and biochemical studies. The protease recognizes a substrate sequence in the RCL, and binds to this to form a Michaelis complex. During cleavage of the peptide bond between Met 358 and Ser 359, an acyl-enzyme intermediate is formed between the carboxyl group of Met 358 on the N-terminal side of the bond and the active site serine of α_1 PI, with release of the polypeptide chain of the serpin C-terminal

to the cleaved bond. This triggers a large conformational change in the section of the RCL N-terminal to the cleaved bond, which moves 70 Å and inserts into the A sheet of α_1 PI between the two parallel strands, generating a 5-stranded antiparallel β -sheet (Figure 3(b)). The RCL carries the covalently attached protease, which is pulled against the body of the serpin, disrupting the catalytic triad by drawing away the catalytic serine (Huntington *et al.*, 2000). While both the RCL and A β -sheet play key roles in the protease inhibitory activity of serpins, other substructures are also important for the conformational change, including the 'hinge' (located in the N-terminal region of the RCL) and the 'breach' (the point in β -sheet A where the cleaved RCL is inserted). The conformational change generated by RCL cleavage increases the stability of the serpin molecule, reflecting a transition from a 'stressed' to 'relaxed' state. This reflects the metastable nature of the active (native) serpin structure, which is kinetically stabilized but is thermodynamically unstable.

Cysteine proteases

These proteases have a covalent mechanism, similar to serine proteases, involving the formation of a thioester bond between the active site cysteine and the carboxyl group of the cleaved peptide bond. The structure of the cleaved form of cytokine response modifier A (CrmA, an anti-apoptotic caspase inhibitor produced by cowpox virus) shows the RCL inserted into sheet A, suggesting that the mechanism of caspase

Figure 3 Ribbon structures of bovine α_1 PI (a) and its inhibitory complex with trypsin (b), showing the structural changes produced during inhibition. β -Strands are colored cyan, α -helices in orange, and other regions in yellow. The region of α_1 PI that is colored in dark blue, initially part of the reactive center loop (RCL), is inserted as an extra strand in β -sheet A. Changes in trypsin are highlighted by superimposing native trypsin (blue) on inhibited trypsin in the complex (pink). Image (a) was generated from PDB file 1QLP and image (b) from PDB 1EZK and 4I8G using Chimera (Pettersen *et al.*, 2004).

inhibition is closely similar to that of serine proteases by other serpins (Renatus *et al.*, 2000).

Activation and Latency

The activities of some serpins, including AT, are modulated by sulfated oligosaccharides, such as heparin. Native AT is a poor inhibitor of thrombin because the key residue of the RCL, Arginine 394, points toward the main body of the inhibitor. The binding of heparin induces a conformational change that releases the arginine and greatly enhances inhibitory activity. In some serpins, the carbohydrate bridges the inhibitor and its target protease. Also, most serpins can undergo a spontaneous structural change to a relaxed, inactive, structure in which the RCL is inserted into the A sheet without cleavage; an extra strand can be added also by rearranging a different part of the serpin structure (e.g., an α -helix). This limits the biological lifetime of some serpins as active inhibitors.

Biological Functions

The irreversible inactivation of proteases by serpins is singularly important in controlling the activity of protease cascades that require stringent regulation, such as blood coagulation and fibrinolysis, and cytosolic proteolysis, that can lead to apoptosis. AT has a crucial role in terminating the coagulation process, being an inhibitor of the intrinsic pathway, in which it inhibits activated forms of thrombin (Factor II), Factor VII, Factor X, Factor IX, Factor XI, and Factor XII. Although α 1PI can inhibit trypsin and other serine proteases, its biological target is leukocyte elastase, particularly in the lung, where excess proteolytic activity can lead to tissue degradation and emphysema. Plasminogen activator inhibitor-2 (PAI-2) has both extracellular and intracellular functions. In the extracellular environment it functions in regulating fibrinolysis through its inhibitory action on plasminogen activators, and has also been reported to have roles in tumor cell metastasis and embryo implantation. The cytoplasmic form of PAI-2 has been shown to interact with and inhibit the proteasome, thereby promoting apoptosis. Other cytoplasmic serpins have been shown to regulate necrosis and apoptosis.

Disease Aspects

The metastable character of the native serpin structure and its tendency to undergo conformational changes are linked to misfolding diseases (serpinopathies) caused by mutations in several human serpins (Roussel *et al.*, 2011). Homozygotes with mutations in α 1PI (S and Z variants) have low circulating levels of the inhibitor and a predisposition to emphysema because of lung damage produced by unregulated leukocyte elastase. The Z variant polymerizes in the endoplasmic reticulum of the liver, its site of synthesis, through a domain-swapping mechanism in which the RCL of one molecule inserts into β -sheet A of another. The accumulation of aggregates of the protein causes hepatocyte cell death and cirrhosis. Mutations in neuroserpin cause familial encephalopathy involving seizures and dementia through a similar polymerization mechanism that generates inclusions in neurons (Miranda *et al.*, 2008). Polymerization is also a feature of

thrombosis arising from mutations in AT. Hereditary C1 esterase inhibitor deficiency is an autosomal dominant disorder caused by mutations in the serpin, C1 esterase inhibitor, that variously lead to low levels of the protein in the circulation or a dysfunctional inhibitor. The symptoms, mostly attributed to inadequate regulation of kallikrein and overproduction of bradykinin, include swelling of skin and mucous membranes including face, abdominal organs and the upper airways; laryngeal edema can produce asphyxiation.

Tissue Inhibitors of Metalloproteinases

These extracellular metalloproteinase inhibitors are widely distributed in animals. Humans have four tissue inhibitors of metalloproteinases (TIMPs), numbered based on their order of discovery, and about 40% identical in sequence. TIMP-1 was first identified as an erythroid potentiating protein, and subsequently purified as an inhibitor of fibroblast collagenase. TIMPs are high affinity, slow-binding inhibitors of the matrix metalloproteinases (MMPs), members of family M10 in the MEROPS database. TIMPs show little discrimination between different MMPs, but TIMP-1 is a relatively weak inhibitor of the membrane-type MMPs (MMP-14, MMP-16, and MMP-24) and MMP-19. TIMP-3 inhibits more metalloproteinases than the other TIMPs, being a potent inhibitor of some important disintegrin-metalloproteinases (MEROPS family 12), particularly a disintegrin and metalloproteinase domain-17 (ADAM-17) (TNF- α -converting enzyme or tumor necrosis factor- α converting enzyme (TACE)), the principle sheddase of mammalian cells, and a disintegrin and metalloproteinase domain with thrombospondin type 1 domains (ADAM-TS- 4 and -5), (aggrecanases-1 and -2).

Structures

Mammalian TIMPs have two domains with larger (~125 residue) N-terminal domains and smaller (~65 residue) C-terminal domains; each domain contains six cysteines and is stabilized by three disulfide bonds (Figure 4).

The N-terminal domains can be expressed separately and fold to form fully active MMP inhibitors. The fact that TIMP-like molecules from nematodes and bacteria do not have C-terminal domains suggests that TIMPs evolved from single-domain ancestors. TIMP C-domains mediate interactions with pro-MMPs in which they interact with the hemopexin domains of the zymogens. Crystallographic structures have been determined for full-length TIMP-1 and TIMP-2 as well as N-TIMP-1 and N-TIMP-3 in complexes with active MMPs. The structure of free TIMP-2 is also known. The N-domains consist of a five-stranded twisted β -barrel with three α -helices, an OB (oligonucleotide and oligosaccharide binding) fold that also found in netrins, agrin, and some complement proteins. TIMP C-domains have a pair of parallel β -strands and two antiparallel strands separated by an α -helix and are closely packed against the N-domains.

Mechanism of Inhibition of MMPs

TIMPs interact directly with the active sites of MMPs in a quasi-substrate mode, denying access to substrates. The core of the

Figure 4 Ribbon structure of the complex of N-TIMP-1 with the catalytic domain of MMP-1. The core of the TIMP interaction site around the Cys1-Cys70 disulfide bond is colored orange and the catalytic Zn^{2+} is pink. The image was generated from PDB: 2JOT using Chimera (Pettersen *et al.*, 2004).

reactive site in the inhibitor is formed by the N-terminal five residues of the N-domain (Cys¹-Thr-Cys-Val-Pro⁵ in TIMP-1) and a five-residue loop (Met⁶⁶-Glu-Ser-Val-Cys⁷⁰ in TIMP-1) between the third and fourth β -strands that is attached to the N-terminal Cys by a disulfide bond. These two regions form a surface ridge that inserts into the MMP active site and is the core of the interaction site, making about 70% of the interactions between the two proteins. The N-terminal Cys sits above the catalytic Zn^{2+} and interacts with it through the α -amino group and carbonyl groups, displacing the water molecule that acts in peptide bond cleavage, while residue 2 (Ser or Thr in mammalian TIMPs) interacts with the P1' specificity pocket of the protease. Residues 3-5 of the TIMP interact with the S2', S3', and S4' subsites of the protease, while residues 68 and 69 (TIMP-1 numbering) interact with the S2 and S3 subsites (Gomis-Ruth *et al.*, 1997; Li *et al.*, 2005). These interactions are conserved in all structurally characterized inhibitory TIMP/MMP complexes. Additional interactions involve loops between the first and second β -strands, a region around the fifth Cys in the protein that is fastened to the core by a disulfide bond with Cys3, and contacts involving the C-domain; these vary in extent and significance in different TIMP/MMP complexes, partly owing to structural differences between TIMPs.

Interactions with pro-MMPs

These interactions are more specific than those with active forms of MMPs: TIMP-1 and TIMP-3 interact with pro-MMP-9

and TIMP-2, TIMP-3, and TIMP-4 can bind to pro-MMP-2. Complexes of TIMPs with pro-MMPs involve the C-domain of TIMP, so that the TIMP N-domains remain available to inhibit active MMPs. The structure of the TIMP-2/pro-MMP-2 complex shows two interactions with the 4-bladed MMP-14 β -propeller hemopexin domain. One involves a loop between the two β -strands of TIMP-2 and the C-terminal blade while the second is between the tail of the TIMP-2 molecule, C-terminal to the last cysteine, and the region between two blades (Morgunova *et al.*, 2002).

Biological Functions

Metalloproteinase inhibition is important for preventing unregulated cleavage of extracellular matrices and uncontrolled shedding of the extracellular domains of cell membrane proteins, including soluble forms of tumor necrosis factor α (TNF- α). Uncontrolled turnover of the proteoglycan, aggrecan, and type-II collagen results in cartilage degradation, leading to osteoarthritis, while excess levels of shed TNF- α can cause inflammatory diseases, notably rheumatoid arthritis. Disruptions of the balance between MMP activity and TIMP production are linked to other disease processes arising from excessive matrix degradation including cancer metastasis, cardiovascular, neurological and kidney diseases, and tissue ulceration.

Functions of TIMPs other than protease inhibition include a role of TIMP-2 in the activation of pro-MMP-2 by MMP-14. Initially, TIMP-2 binds the C-terminal hemopexin domain of pro-MMP-2. The N-domain of TIMP-2 in this complex interacts with an active MMP-14 anchored on the cell membrane and the pro-MMP-2 molecule in this ternary complex is activated by cleavage of its pro-domain by a second MMP-14 molecule. This process is facilitated by interactions between the hemopexin domains of the two MMP-14 molecules. Both TIMP-3 and TIMP-4 can also bind to pro-MMP-2 but inhibit its activation.

Angiogenesis involves cell migration and blood vessel formation, both of which require MMP proteolysis; consequently, TIMPs have anti-angiogenic properties. However, the mechanisms of these effects do not simply involve protease inhibition but also signaling by TIMP-2/integrin interactions and TIMP/VEGF (vascular endothelial growth factor) interactions. TIMP-3 has pro-apoptotic effects on cancer and other cells that are thought to arise from its inhibition of sheddases, including ADAM-17, resulting in the stabilization of death receptors (TNF receptor 1, FAS and TNF-related apoptosis-inducing ligand and receptor 1 (TRAIL-R1)). However, the availability of free TIMP-3 is limited because of its tight binding to the matrix and sequestration by endocytosis (Brew and Nagase, 2010). TIMPs have multiple activities that appear to be unrelated to their interactions with metalloproteinases (reviewed by Stetler-Stevenson, 2008) including effects of TIMP-1 and TIMP-2 on cell growth and differentiation, and angiogenesis. These appear to be mediated by interactions with cellular receptors including TIMP-1 interactions with the tetraspanin, CD63, and TIMP-2 with $\alpha_3\beta_1$ integrin.

Disease Aspects

Mutations in the C-domain of TIMP-3 cause of Sorsby fundus dystrophy (SFD) (Weber *et al.*, 1994), the only human disease

definitively linked to TIMP mutations. SFD is an autosomal dominant disorder that results in early-onset macular degeneration with a pathology similar to AMD. The SFD mutations in TIMP-3 do not affect its inhibitory activity but are localized in the non-inhibitory C-domain. They include missense and truncation mutations that result in unpaired cysteines, suggesting reduced stability. Various mechanisms have been proposed for the disease including increased TIMP-3 accumulation in Bruch's membrane, an extracellular matrix between the retina and choroid. Thickening of this matrix, also seen in AMD, may disrupt nutrient transport.

Overview of Blood Coagulation

Hemostasis is the process that maintains blood in a fluid state and confines it to the circulatory system. The normal hemostatic system limits blood loss by highly regulated interactions between components of the vessel wall, circulating platelets, and plasma proteins ([Figure 1](#); [Table 1](#)).

Figure 1 Balance of hemostasis: the interaction of blood platelets, vascular endothelial cells, and blood plasma-coagulation factors are needed for successfully achieving a blood clot. Many different circumstances that are either acquired/environmental or inherited lead to perturbation of hemostasis and pathological conditions to promote hemorrhage or thrombosis.

Historically, primary hemostasis described the role of the cells (platelets and endothelial cells) in blood coagulation, secondary hemostasis described the role of the blood coagulation system, and tertiary hemostasis described the dissolution of the clot by fibrinolysis. There are numerous diseases in which the hemostatic system becomes dysregulated, leading either to hemorrhage or intravascular thrombosis and embolism.

Primary Hemostasis

Platelet Production

Following injury or damage to a blood vessel, several physiological pathways converge to prevent the loss of excessive amounts of blood and to allow the vessel to be repaired. The platelet is one of the first responders to the site of vascular injury, and it plays a significant role in the formation of a plug to stem the loss of blood from the vessel. Platelets are formed within the bone marrow from their precursors, megakaryocytes. The coordinated effort of several cytokines and growth factors, most importantly thrombopoietin (TPO), leads to the maturation of hematopoietic stem cells into megakaryocytes. TPO plays several important roles in the formation of the megakaryocyte, including increasing the production of megakaryocyte precursors, inhibiting megakaryocyte apoptosis, and promoting megakaryocyte maturation ([Vainchenker et al., 2014](#)). Mature megakaryocytes extend projections into the sinusoids of the bone marrow where small pieces of the megakaryocytes are sheared off by flowing blood and become anucleate, granular platelets.

Table 1 Hemostatic and fibrinolytic proteins, characteristics and physiological roles/pathological processes

Protein	Plasma (mcg ml ⁻¹)	Chromosome loci	Physiological pathway	Pathological process (deficiency or mutation)
α_2 -Antiplasmin	70	18p11.1-q11.2	Anti-fibrinolysis	Hemorrhage
Antithrombin	150–400	1q23-q25	Anticoagulation	Thrombosis
Endothelial protein C receptor	–	20q11.22	Anticoagulation	Thrombosis
Factor V	5–10	1q21-q25	Coagulation	Hemorrhage ^a
Factor VII	0.5	13q34	Coagulation	Hemorrhage
Factor VIII	0.1–0.2	Xq28	Coagulation	Hemorrhage ^b
Factor IX	4–5	Xq27.1-q27.2	Coagulation	Hemorrhage ^b
Factor X	8–10	13q34	Coagulation	Hemorrhage
Factor XI	5	4q32-q35	Coagulation	Hemorrhage

Platelets contain two types of granules: alpha and dense granules. Alpha granules contain chemokines and growth factors, such as platelet-derived growth factor, and proteins involved in primary and secondary hemostasis, including von Willebrand factor (vWF), fibrinogen, and factor V (Blair and Flaumenhaft, 2009). Dense granules contain mediators of primary hemostasis, such as ADP and ATP, serotonin and calcium, which is a required cofactor for coagulation (McNicol and Israels, 1999). Since platelets are anucleate and are mostly incapable of undergoing protein synthesis, the contents of their granules are predetermined by the megakaryocyte from which they bud off. However, there are certain proteins that are taken up into granules via receptor-mediated endocytosis (Machlus *et al.*, 2014; Thon and Italiano, 2012).

Platelet Structure and Function in Primary Hemostasis

Primary hemostasis culminates in the formation of a platelet plug at the site of vascular injury. The proper formation of the platelet plug requires the function of several platelet surface glycoprotein receptors (Varga-Szabo *et al.*, 2008; Cimmino and Golino, 2013). These receptors serve to initially adhere platelets to the vessel wall at the site of injury, as well as to recruit

and aggregate nearby platelets to aid in the growth of the platelet plug.

In the absence of vessel injury, the endothelium of the blood vessel provides a protective anticoagulant surface and synthesizes anticoagulant proteins to prevent aberrant thrombosis. Upon injury, subendothelial proteins, such as type IV collagen, are exposed to flowing blood. Platelets adhere to the exposed subendothelium via vWF, a large multimeric glycoprotein produced by endothelial cells and degranulating platelets. vWF tethers platelets to the damaged endothelium through binding of the vWF A1 domain to glycoprotein Ib–glycoproteinV–glycoprotein IX complex on the surface of the platelet. Additionally, platelets can bind directly to exposed subendothelial collagen via glycoprotein VI on their surface. Through these two interactions, platelets are able to adhere to the site of vessel injury and begin the formation of a hemostatic plug (Varga-Szabo *et al.*, 2008; Andrews and Berndt, 2008; Firbas *et al.*, 2010; Lenting *et al.*, 2010). Once bound at the site of injury, the platelet undergoes an activation characterized by the rearrangement of cytoskeletal elements such as actin and myosin, which leads to a change in the platelet shape, along with prominent filopodia formation, and the release of granule contents from both the alpha and dense granules. Several mediators, including ADP

Figure 2 Blood coagulation is typically initiated following vascular injury by platelet adhesion, activation, and aggregation (primary hemostasis). The coagulation pathway (secondary hemostasis) is composed of a cascade of proteases that further activate platelets and ultimately generates thrombin to cleave fibrinogen to fibrin. Serine protease inhibitors (Serpins and Kunitz-type inhibitors) target activated coagulation proteases. The protein C pathway inhibits the further propagation of thrombin by inactivating FVa and FVIIIa. The sustained presence of a thrombus is regulated by the fibrinolysis pathway, which controls fibrin degradation. Accompanying feedback loops and other cofactors are not shown to maintain the simplicity of the schematic.

and serotonin, are released from the activated platelet and aid in the recruitment of additional platelets to the site of injury by positive feedback mechanisms (Cimmino and Golino, 2013). Once activated, glycoprotein IIb/IIIa (GP_{IIb/IIIa}) becomes exposed on the platelet surface. The exposure of GP_{IIb/IIIa} allows for the platelet to bind to circulating fibrinogen, another key coagulation protein. Fibrinogen is a bivalent molecule, and each fibrinogen molecule is capable of binding to two activated platelets. This binding effectively bridges activated platelets at the site of injury and increases the area and volume of the platelet plug. Finally, the exposure of phosphatidyl serine (PS) on the aggregated platelet surface catalyzes the conversion of fibrinogen to fibrin through the coagulation pathway, termed secondary hemostasis.

Secondary Hemostasis

Initiation Phase

Upon perturbation or injury to the vessel wall, subendothelial tissue factor (TF) expressed by cells such as fibroblasts and smooth muscle cells is exposed to the flowing blood, becoming available for complex formation with circulating activated factor VII (FVIIa) (Figure 2; Mann, 2003a; Butenas and Mann, 2002; Owens and Mackman, 2010; Williams and Mackman, 2012). This TF–FVIIa complex initiates the coagulation pathway by activation of both factor X (FX) to activated

factor X (FXa) and factor IX (FIX) to activated factor IX (FIXa). FXa bound to its cofactor, activated factor V (FVa), then cleaves prothrombin to its active form, thrombin. This is the initiation phase of coagulation (Hoffman and Monroe, 2001; Monroe and Hoffman, 2006).

The relatively small amount of thrombin generated during the initiation phase can activate factor XI, factor VIII, and factor V, and can activate platelets by cleavage of the protease-activated receptors on the platelet surface. In addition, thrombin stimulates microparticle (MP) release from platelets and circulating monocytes (Owens and Mackman, 2011). Rich in TF and PS, MPs support FXa generation and are critical in promoting thrombin generation and further platelet activation. Furthermore, inorganic polyphosphate (polyP) is secreted upon platelet activation and potentially augments several of the initiation phase components of blood coagulation (Smith *et al.*, 2006; Smith and Morrissey, 2014).

Propagation Phase

Greater activation of FIX by FXIa, and of FXa occurs on the PS-rich platelet surface by the FIXa and FVIIIa (factor VIII (activated)) complex with its substrate FX, also known as the ‘tenase complex’ (Figure 2; Table 1). Also on the platelet surface, FXa binds with its cofactor, FVa and its substrate prothrombin (all together referred to as the ‘prothrombinase complex’), generating a large volume burst of thrombin (Figure 2; Hoffman and Monroe, 2001; Monroe and Hoffman,

2006; Mann, 2003b). This is termed the propagation phase of coagulation and this process cycles to produce large amounts of thrombin that cleaves circulating fibrinogen to fibrin, which is stabilized and made insoluble through fibrin cross-linking by the transglutaminase, activated factor XIII (FXIIIa) (Aleman *et al.*, 2014).

Regulation of Blood Coagulation

As aberrant or sustained clotting can be pathological, several important anticoagulant and fibrinolytic pathways also regulate blood coagulation and clot dissolution. The vascular endothelium is an important tissue in both venous and arterial circulation, providing the barrier between the luminal blood and intima of the vessel wall. As the only noncirculating cell type in direct contact with the flowing blood, endothelial cells are pivotal in preventing thrombosis while maintaining hemostasis (Verhamme and Hoylaerts, 2006; Sagripanti and Carpi, 2000). Anticoagulant in nature, endothelial cells produce an array of proteins and substances designed to regulate thrombin production.

The protein C pathway is an essential anticoagulant regulatory pathway designed to inhibit the propagation of thrombin (Figure 2; Esmon, 2000, 2003). As part of their antithrombotic surface, vascular endothelial cells produce thrombomodulin (TM), a transmembrane glycoprotein that binds to thrombin in the presence of endothelial protein C receptor (EPCR), which binds zymogen protein C. The TM–thrombin complex cleaves protein C bound to EPCR to activated protein C (APC) (Figure 2). APC (a serine protease) can then interact with its cofactor, protein S, to proteolytically inactivate FVa and FVIIIa, down-regulating the further generation of thrombin.

Vascular endothelial cells also produce heparan sulfate and dermatan sulfate, which increase the efficiency of thrombin inhibition by antithrombin and other serine protease inhibitors (Serpins) (Figure 2; Tovar *et al.*, 2005; Rau *et al.*, 2007; Rein *et al.*, 2011). Endothelial cells synthesize tissue factor pathway inhibitor (TFPI), which is a Kunitz-type protease inhibitor that inhibits FXa and, in a FXa-dependent manner, the FVIIa–TF complex (Figure 2; Broze, 1995). Endothelial cells also produce key platelet inhibitors, including prostacyclin and nitric oxide (NO), limiting the availability of lipids for coagulation factor complex formation (Pate *et al.*, 2010).

In addition to pathways that control clot formation and prevent the generation of occlusive thrombi, fibrinolysis must also be regulated. The fibrinolytic pathway dictates whether clots are sustained or dissolved (Figure 2; Rijken and Lijnen, 2009; Fay *et al.*, 2007; Rein-Smith and Church, 2014). Endothelial cells and trapped leukocytes release tissue and urokinase plasminogen activator (tPA (tissue-type plasminogen activator) and uPA (urokinase plasminogen activator), respectively), proteases which activate plasminogen to plasmin. Plasmin is a serine protease that cleaves cross-linked fibrin to produce fibrin degradation products, which are easily swept away and degraded in flowing blood. Plasmin is inhibited by α_2 -antiplasmin (α_2 -AP) and plasminogen activator inhibitor-1 (PAI-1) is the primary inhibitor of tPA and uPA. PAI-1 and α_2 -AP are Serpins that bind tightly to the active site of these target proteases, therefore inhibiting fibrinolysis.

Coagulation Disorders Overview

There are a variety of pathologies secondary to genetic or acquired risk factors that cause dysregulation of coagulation pathways. The most common coagulation disorders that cause either bleeding or thrombotic phenotypes will be discussed.

Coagulation Disorders – Bleeding

Defects in platelet production

Decreases in platelet number, or thrombocytopenia, can be caused by defects in several systems in the body. Drugs, chemotherapy, hematological malignancy of the bone marrow, or vitamin deficiencies may inhibit the production of platelets in the bone marrow. Normal platelet counts generally range from 150 to 450×10^9 cells/ μ l. Epistaxis, mucocutaneous bleeding, bruising, petechiae, and heavy menses in females are commonly observed symptoms for patients with thrombocytopenia.

Alternatively, platelets may be produced normally, but destroyed prematurely by an immune system malfunction, as in the case of immune thrombocytopenic purpura (ITP). In ITP, antibodies against platelet surface antigens are produced, leading to immune-mediated destruction of the platelets in the spleen. ITP may be asymptomatic or may manifest with symptoms including purpura, petechiae, and mucocutaneous bleeding. Treatment for ITP includes the use of corticosteroids to inhibit autoantibody formation, and splenectomy to decrease antibody formation and platelet destruction (Cines *et al.*, 2014).

Thrombocytopenias can also be caused by defects in the processing of vWF, a specific thrombocytopenia known as thrombotic thrombocytopenic purpura (TTP). The etiology of TTP is known to be defects in ADAMTS13, a protease responsible for the cleavage of ultra-long vWF (ULVWF) secreted from the endothelium into smaller, less adhesive fragments. Deficiency, dysfunction, or antibodies against ADAMTS13 lead to the accumulation of ULVWF in the circulation. As ULVWF is a 'sticky' protein, its buildup leads to aberrant platelet adhesion and activation in the microvasculature, microvascular thrombosis, and consumption of platelets. Treatment for TTP is plasmapheresis in order to remove autoantibodies to ADAMTS13 (Kremer Hovinga and Lammle, 2012).

Defects in platelet function

Symptomatically, platelet dysfunction may resemble defects in platelet number, and may include epistaxis, mucocutaneous bleeding, easy bruising, and petechiae. Numerous qualitative platelet defects have been described, most of which affect the adhesion of, secretion from, or aggregation of platelets (Nurden and Nurden, 2014). Disorders of platelet adhesion can arise due to several factors, most notably abnormal or absent vWF (von Willebrand disease (vWD)), defects in GpIb (Bernard-Soulier Syndrome), or abnormalities of the sub-endothelial connective tissues (Ehlers–Danlos Syndrome). vWD is a particularly interesting disorder in that not only do patients have clinical symptoms consistent with a primary hemostatic defect due to vWF's role in platelet adhesion, but they also display symptoms associated with secondary

hemostatic defects due to vWF's role as a carrier protein for FVIII. Several types of hereditary and acquired vWD have been described, and their classification is based upon the nature of the defect. Type 1 vWD accounts for approximately 60–80% of all vWD and is defined as decreased levels of circulating vWF. However, many of these patients will lead a nearly normal life, requiring intervention only when undergoing surgery. When treatment is necessary, the most commonly used therapies are DDAVP (desmopressin) to stimulate the release of vWF and FVIII from endothelial cells, and the administration of cryoprecipitate to increase circulating FVIII and vWF (Lillicrap, 2013).

Hemophilia

Among the hereditary bleeding disorders, the best known are hemophilia A and B, which are X-linked recessive traits that affect the production of FVIII and FIX, respectively. Normal hemostasis requires between 25% and 33% of functional FVIII and FIX, and symptomatic patients typically have less than 5% of functional FVIII or FIX, with a close clinical correlation between severity of symptoms and factor levels (Hoyer, 1994). Patients with hemophilia typically bleed into muscles (hematomas), joints (hemarthroses), and body cavities following injury, as opposed to the mucocutaneous bleeding seen in the setting of primary hemostatic defects. Additionally, hemophilia A and B have clinically indistinguishable symptoms; therefore, direct measurements of FVIII and FIX activity should be undertaken to determine which type of hemophilia is present. Several treatment options are available for patients with hemophilia A and B including recombinant FVIII and FIX, plasma-purified products enriched in FVIII and FIX, factor concentrates, and hopefully in the near future, gene therapy (Schramm, 2014; Hoyer, 1994).

Vitamin K deficiency

Vitamin K is a fat-soluble vitamin that is absorbed from the diet in the small intestine and is stored in the liver. Vitamin K can also be synthesized by endogenous bacterial flora of the small intestine and colon. The three most recognized causes of vitamin K deficiency result from inadequate dietary intake, malabsorption in the gut, or impaired uptake and storage by the liver due to hepatic disease (Burke, 2013).

The process of sequential oxidation and reduction of vitamin K, known as the vitamin K cycle, plays a key role in the formation of functional coagulation proteases and cofactors, including prothrombin, FVII, FIX, FX, and proteins C and S. These proteins contain posttranslationally modified γ -carboxylated glutamate residues (Gla), commonly known as Gla residues. Due to their ability to bind calcium, Gla residues are vital to the proper folding of these proteins as they participate in intrachain linkages. Additionally, Gla residues are required for the binding of these coagulation factors to the surface of phospholipid membranes, namely platelets, where they can form protein complexes. The oxidation of vitamin K provides the energy necessary for the formation of Gla residues from glutamic acid residues. As such, vitamin K deficiency leads to deficiencies of prothrombin, FVII, FIX, FX, and proteins C and S (Greer, 2010). Manifestations of vitamin K deficiency may include easy bruising, mucocutaneous bleeding, and these

symptoms can be ameliorated by administration of parenteral vitamin K (McNinch, 2010).

Trauma-induced coagulopathy

Among the acquired risk factors for bleeding disorders, injury is the most common. Traumatic injuries cause 10% of deaths worldwide, with hemorrhage accounting for 40% of these fatalities (Norton and Kobusingye, 2013; Brohi *et al.*, 2007). Trauma-induced coagulopathy (TIC) is characterized by excessive and sustained bleeding, sometimes disproportionate to injury severity, affecting 25% of trauma patients. Patients suffering from TIC are at five-fold greater risk of death and require massive transfusions to replace lost blood volume (Brohi *et al.*, 2007; D'Angelo and Dutton, 2010). The mechanisms driving TIC are more complex than hemodilution or anatomic disruption. The TIC pathology is multifactorial and arises secondary to hemorrhage, tissue injury, hypoperfusion, acidosis, and hypothermia. It subsequently results in endothelial activation, platelet dysfunction, activation of the protein C system, and severe hyperfibrinolysis. Such simultaneous dysregulation of coagulation pathways results in substantial bleeding (Cardenas *et al.*, 2014). Current research in TIC is focused on methods of early and accurate diagnosis of TIC and identifying the most beneficial points of pharmacologic intervention.

Coagulation Disorders – Thrombosis

Arterial thrombosis – Overview

Coronary heart disease (CHD), including both myocardial infarction and stroke, is the leading cause of death among Americans. Approximately 720 000 Americans suffer from CHD annually and results in 380 000 deaths each year (Centers for Disease Control and Prevention, 2015). Both diseases are complications associated with arterial thrombosis, typically following atherosclerotic plaque rupture. Upon exposure of plaque contents to flowing blood, occlusive and migratory clots form very rapidly and are highly dependent on platelet activation. This results in ischemia of heart or brain tissue and is potentially fatal if not treated immediately (Massberg *et al.*, 2003). Many risk factors for arterial thrombosis are acquired and include age, diet, exercise, smoking, blood pressure, diabetes, and cholesterol levels. Further discussion of genetic and acquired risk factors is provided below.

Deep vein thrombosis – Overview

Deep vein thrombosis (DVT) is characterized by the formation of occlusive or semi-occlusive thrombi typically in the deep veins of the limbs. The most serious and potentially fatal complication of a DVT is pulmonary embolism (PE). DVT and PE are collectively referred to as venous thromboembolism (VTE). The incidence of VTE is approximately 1 in 1000, with between 350 000 and 600 000 individuals affected by this disease each year in the United States (Branchford *et al.*, 2012; Office of the Surgeon General (US); National Heart, Lung, and Blood Institute (US), 2008). Virchow's triad can be used to explain the etiology of thrombosis: changes in blood vessel due to endothelial injury, secondary to diseases like atherosclerosis, trauma, or chronic inflammation; changes in blood

constituents due to primary hypercoagulability or acquired hypercoagulability; and changes in blood flow such as caused by stasis or vessel turbulence especially behind venous valve pockets (Wolberg *et al.*, 2012). There are many risk factors for VTE, both genetic and acquired/environmental, which will be discussed in further detail with particular emphasis on age, as the population of elderly individuals in the United States is unique and rapidly growing.

Factor V Leiden

The most common genetic risk factor for venous thrombosis is the Factor V Leiden mutation. Factor V (FV) is a key component of the prothrombinase complex and regulates coagulation through its role in thrombin generation. The FV Leiden mutation results in resistance to APC-induced anticoagulation. FV Leiden results from a single point mutation in the factor V gene (guanine to adenine at nucleotide 1691), which leads to a single amino acid change (FV Arg506Gln). The FV Leiden mutation not only slows the inactivation of FVa by APC, but also alters a cofactor generated during APC-mediated cleavage of unactivated FV. Thus, resistance to APC inactivation results in sustained and uninhibited thrombin generation by these proteins. Approximately 3–7% of individuals in the United States carry the FV Leiden mutation and it predominantly affects Caucasians (Shaheen *et al.*, 2012). Heterozygotes are at 2–7 times greater risk of VTE compared to individuals without the FV Leiden mutation, while homozygotes are at a striking 40- to 80-fold higher risk of VTE (De Stefano *et al.*, 2002).

Prothrombin G20210A

The second most common polymorphism predisposing patients to VTE is the prothrombin G20210A mutation. As the precursor to thrombin, prothrombin is a procoagulant zymogen essential for effective coagulation. Similar to Factor V Leiden, the prothrombin G20210A mutation predominantly affects Caucasians. Approximately 2–3% of the Caucasian population carries the prothrombin mutation, which is a single substitution of adenine for guanine at the G20210 position resulting in reduced prothrombin degradation and a subsequent increase in circulating plasma levels of prothrombin. This mutation confers a three-fold greater risk of developing VTE (Bauduer and Lacombe, 2005; Johnson *et al.*, 2005).

Plasminogen activator inhibitor-1 (PAI-1)

PAI-1 blood levels are sensitive to many different pathophysiological factors; thus, increased synthesis of PAI-1 contributes to several cardiovascular disease states (Yamamoto *et al.*, 2005; Booth, 1999; Gramling and Church, 2010; Vaughan, 2001, 2005). As an acute phase reactant, PAI-1 blood levels increase in response to vessel injury and inflammatory signaling. Increased PAI-1 levels are associated with coronary artery disease and myocardial infarction (Tjarnlund-Wolf *et al.*, 2012). However, studies examining the association of thrombosis with a polymorphism in the PAI-1 promoter region (4G/5G) that increases PAI-1 expression remain controversial (Ridker *et al.*, 1997; Segui *et al.*, 2000). Use of statins, a class of drugs used to lower cholesterol levels, is associated with a decrease in PAI-1 expression and increase in tPA expression. Use of drug-eluting stents (coated with rapamycin or

paclitaxel) placed in an artery during percutaneous coronary intervention is associated with an increased risk of arterial thrombosis due to an up-regulation of PAI-1 (Muldowney *et al.*, 2007).

Aging

While there are a variety of acquired risk factors for thrombosis including obesity, diabetes, hypertension, injury, pregnancy, and hormone therapy, the strongest and most unchangeable risk factor for both arterial and venous thrombosis is age. Population-based and basic science research has uncovered a variety of age-related changes in blood proteins, cells, and the vasculature that could predispose individuals to thrombosis.

A number of large-scale studies have measured the changes in coagulation factors with respect to age. One of the coagulation proteins most commonly reported to increase with age is fibrinogen, with levels ranging from 250 mg/dL in young, 20-year-old subjects to 300 mg/dL in subjects over 65 years of age (Mari *et al.*, 2008; Meade *et al.*, 1977). As the precursor to fibrin, fibrinogen availability is a key determinant in the formation of stable thrombi.

FVIII levels are also known to increase with age. FVIII, with its cofactor FIXa, is a potent activator of FX. Thus, elevated FVIII has long been believed to be a risk factor for VTE, and as of recently, also for arterial thrombosis (Machlus *et al.*, 2011). A prospective cohort study showed an 11-fold increase in the risk of VTE in individuals with FVIII levels above the 90th percentile (Kytle *et al.*, 2000).

FVIII circulates bound to vWF and as such, age-related increases in vWF have also been observed (Toffler *et al.*, 2005). It was thought that vWF only contributed to the risk of VTE through its association with, or effect on levels of FVIII. However, the 2002 LITE study showed that FVIII and vWF are in fact independent risk factors for VTE (Tsai *et al.*, 2002). Mouse models have recently shown that both vWF and FVIII are independently critical for venous thrombus formation.

The zymogen FIX, a member of the tenase complex with cofactor FVIII, also undergoes an age-dependent increase (Sweeney and Hoernig, 1993). Given its importance in the activation of FX, elevated FIX levels are thought to be a risk factor for VTE. Data from the LETS study concluded that those with FIX levels above the 90th percentile had an odds ratio of 2.3 and were at elevated risk of VTE (van Hylckama Vlieg *et al.*, 2000).

PAI-1 is an important inhibitor of fibrinolysis and elevated levels of this protein have been reported in aging and a variety of other disease states. Data from the Framingham cohort found that PAI-1 antigen levels in plasma went from 19.4 ng/mL in men under 40 years to 24.6 ng/mL in those 70 years and above, with similar increases found in women (Toffler *et al.*, 2005). Elevated PAI-1 levels are positively correlated with the risk of thrombotic events (Prisco *et al.*, 1993; Hamsten *et al.*, 1987).

Interestingly, aging in humans is associated with a decrease in circulating platelet counts, with an estimated decrease of $6 \times 10^9/L$ for every 10 years of age (Biino *et al.*, 2012). It remains unclear whether this decrease in platelet count is due to reduced hematopoiesis, decreased production from megakaryocytes, or increased clearance by the spleen.

Despite the reduction in platelet number, aging is associated with differences in platelet function. While there is very little current data in this area, historical data has given insight into how platelet biology changes with age. Increased platelet aggregation in response to ADP, collagen, and adrenaline has been observed in platelets from aged individuals, in addition to increased ATP release upon collagen stimulation (Kasjanovova and Balaz, 1986; Vilen *et al.*, 1989). Platelets from older individuals also display reduced ADP thresholds for aggregation compared to those from the young, further suggesting they are more sensitive to certain agonists (Gleerup and Winther, 1995). It is thought that this hyperreactivity is due to increased platelet expression of receptors for these agonists (Kasjanovova and Balaz, 1986; Vilen *et al.*, 1989). Platelets from the elderly also produce more thromboxane A₂, which is involved in platelet activation and formation of platelet aggregates (Suehiro *et al.*, 1995; Gleerup and Winther, 1995). This could have clinical implications for treating elderly patients with antiplatelet agents such as clopidogrel, an inhibitor of the platelet P2Y₁₂ receptor for ADP. A recent study found that the linear age-related increase in ADP-induced platelet aggregation was associated with reduced sensitivity to initial clopidogrel treatment (Gremmel *et al.*, 2010).

Aside from biological changes that occur with age in platelets, age-associated changes in endothelial function could also promote platelet hyperreactivity. These include increased endothelial production of vWF, which could result in enhanced platelet tethering to endothelial cell surfaces (Muller *et al.*, 2002). Also, decreased production of endothelial nitric oxide synthase (eNOS) results in down-regulation of NO generation. NO is a potent inhibitor of platelet activation (Yoon *et al.*, 2010). Decreased levels of this important inhibitor could result in dysregulation of platelet activation and the inappropriate release of procoagulant material from platelet granules.

Endothelial dysfunction is a widely accepted consequence of aging and can turn the naturally anticoagulant endothelial cell surface into one that is more procoagulant. Many age-related changes have been reported to occur in the vascular endothelium, one of which is increased vascular permeability. The loss of cell-cell junctions with age results in vascular leakage, exposure of subendothelial proteins (i.e., TF), and leukocyte adhesion (Lum and Roebuck, 2001). Aged endothelial cells also produce more anti-fibrinolytic PAI-1 (Comi *et al.*, 1995) and, in animal models, less anticoagulant TM upon treatment with endotoxin (Starr *et al.*, 2010). There is also increased production and secretion of pro-inflammatory cytokines interleukin-6 (IL-6) and interleukin-1 β (IL-1 β) from aged endothelium, promoting recruitment and binding of leukocytes to the cell surface (Csiszar *et al.*, 2003). Aging is also associated with a loss of eNOS production, resulting in reduced availability of NO to regulate vessel dilation and platelet activation (Yoon *et al.*, 2010).

Conclusions

The hemostatic system is a highly regulated protease pathway involving intracellular and extracellular proteins, circulating

blood cells, and the dynamic vascular endothelium (Figures 1 and 2). Efficient and appropriate hemostasis is crucial to maintaining blood flow and perturbations in this system can cause life-threatening bleeding or thrombotic complications.

Molecular Mechanisms Underlying the Actions of the Complement System

RN Pike and LC Wijeyewickrema, Monash University, Clayton, VIC, Australia

The Complement System

The complement system is a set of 35 defensive proteins that protect our bodies against pathogens and altered self cells (Carroll, 2004). The vital role that the system plays is revealed by the many diseases that we become susceptible to when deficient in one of the proteins from the system (Ricklin *et al.*, 2010). The most evident of these is that humans become highly prone to infection when the complement system is compromised (Degn *et al.*, 2011). Equally, complement plays a major role in causing disease, as the system is involved in most diseases with an inflammatory component to them (Mollnes *et al.*, 2002), giving rise to a broad range of diseases affecting systems ranging from joints to teeth and the cardiovascular system. This has led to a range of complement molecules being targeted in order to control diseases such as atypical hemolytic urinary syndrome, reperfusion injury after acute myocardial infarction, arthritis, and graft versus host disease.

The complement system is initiated by the classical, lectin, and alternative pathways (Duncan *et al.*, 2008; Figure 1). Each of these pathways involves an initial recognition or binding event, in which a pathogen or altered self cell is 'tagged' by a molecule of the complement system. Subsequent to the initial binding event, protease molecules that are either pre-bound to the molecule that mediated the initial binding event or become bound to it, cleave substrates that amplify the initial binding signal (Gros *et al.*, 2008). These amplification events have both local and systemic effects. In local terms, the amplified system is able to induce death to pathogen or self cells by lysing their membranes using the C5–C9 components of the system to perforate the membranes by assembling these components into pore-like structures, causing death of the recognized cell. These cells are also decorated with other molecules assembled onto their surfaces along the way, particularly the cleaved C3b molecule, which flags the cell to receptors on professional phagocytic white blood cells and thus ensures its internalization into these cells and subsequent digestion. This not only removes the cell from the site, but also begins the antigen presentation process by these white blood cells, which provides an extremely important link to adaptive immunity (Dunkelberger and Song, 2010). In systemic terms, chemotactic molecules, particularly C5a, are liberated from tissue in which complement has been activated and taken up by the bloodstream, thus providing a chemotactic gradient to the site of infection or injury. White blood cells are thus alerted to the occurrence and migrate down the chemotactic gradient to the site to carry out functions ranging from phagocytosis (macrophages) to pathogen killing (neutrophils) and induction of an adaptive immune response (dendritic cells and T-cells). Thus the activated complement system potentially brings the entire force of the host's immune system to bear on pathogenic or altered self cells. Unfortunately, this same potent response can become a misguided missile, causing injury to the host and thus disease.

Classical Pathway

The classical pathway of complement (Figure 2) is activated by the C1 complex (Wallis *et al.*, 2010), comprised of six C1q molecules in association with the C1r and C1s serine proteases (Formeris *et al.*, 2012). Binding of C1q molecules to their ligands, classically antibody–antigen complexes, causes auto-activation of C1r, which in turn cleaves C1s to activate it. The activated C1s cleaves the C4 and C2 complement components in turn, allowing C4b and C2a to assemble into the C3 convertase complex. The proteolytic C2a component then cleaves C3 attracted to the convertase complex by a binding site on the C4b component. The cleaved C3b component remains bound to the complex to form the C5 convertase complex, in which C2a cleaves C5 recruited to the complex via binding sites on C4bC3b. The resultant C5b product is able to scaffold the assembly of the C6–C9 components into the MAC as noted above. It is worth noting that the C3 and C4 complement components belong to the group of molecules containing thioester groups (Law and Dodds, 1997), which are activated upon their cleavage and facilitate binding of these molecules to membrane proteins. Interestingly, while C5 belongs to this group of molecules as judged by sequence homology, it has lost the thioester group pivotal to the functions of C3 and C4 (Discipio, 1981). This binding mechanism of C3 and C4 results in their localization to the point of activation of the system, a crucial mechanism to prevent mislocalisation of the activated system. The proteolytic cleavage of the C3–C5 components also gives rise to the C3a, C4a, and C5a peptide components which play a key role in activating the rest of the immune system as noted above.

The C1 complex that initiates the classical pathway is composed of six C1q molecules, each in turn composed of three chains, associated with two C1r and two C1s protease molecules (Gaboriaud *et al.*, 2004). Electron microscopy and structural studies of the C1 complex and components have given some insights into the presumed structure of C1, with these studies revealing a structure somewhat reminiscent of an inverted bunch of tulips, consisting essentially of three regions: the neck, stalks, and heads. From the N-terminus, the C1q molecules are composed of collagen-like triple helices wound together into a super-helix in the neck and stalk regions and three globular heads. The neck regions of all six molecules are bound together, through a combination of covalent disulfide bonds and non-covalent bonds. The super-helices then splay away from each other in the stalk region to yield 6 individual stalks. Finally, the globular heads, responsible for binding to ligands, are found at the C-terminal end of the structure (Gaboriaud *et al.*, 2003). Recent new data indicates that full activation of this hexameric arrangement of C1q molecules is achieved when the C1 complex binds to the constant fragment 'tails' of six immunoglobulin molecules hexamerically arranged due to non-covalent bonding that occurs between their Fc segments after binding to their antigenic targets (Diebolder *et al.*, 2014).

Figure 1 The three major complement activation pathways: classical, lectin, and alternative. The classical and lectin pathways are activated when recognition complexes bind to cognate targets, such as antibody–antigen complexes (C1 complex) or carbohydrate arrays on microbial surfaces (lectins). They use associated serine proteases, such as C1s and MASP-2, to cleave C2 and C4 to generate the C3 convertase (C4bC2a) and which in turn cleaves C3 to yield the C5 convertase (C4bC2aC3b). The alternative complement pathway begins with the spontaneous activation of C3 and requires fB and factor D to form the C3 convertase (C3bBb) and then the C5 convertase (C3bBbC3b). All three pathways converge at C3, which is converted into C3a and C3b. The further formed C5 convertase cleaves C5 into C5a and C5b. C5b scaffolds the assembly of the membrane-attack complex (MAC), composed of C5b, C6, C7, C8, and many copies of C9. The activation of the system thus results in the killing of the pathogen via the MAC, opsonization of the organism for phagocytosis and the released C3a and C5a result in activation of white blood cells, including those controlling the adaptive immune response. The complement system is controlled by many inhibitors (blue boxes).

The protease component of the C1 complex is composed of two molecules each of C1r and C1s, formed into a heterotetramer. C1r and C1s are both serine proteases that are composed of six domains arranged into two modules: (1) the non-catalytic module, composed of the CUB1-EGF-CUB2 domains, and (2) the catalytic module made up of the complement control protein-like (CCP1-CCP2-serine protease (SP)) domains. The non-catalytic module of each enzyme binds calcium ions and is vital for the binding of the enzymes

to each other and to C1q (Venkatraman Girija *et al.*, 2013). Recent data suggests that the CUB1-EGF-CUB2 modules of the two C1s molecules form the core of the molecular arrangement of the proteases in the inactive C1 complex, with the same regions of the two C1r molecules then arranged on the outside of this C1s core (Brier *et al.*, 2010; Bally *et al.*, 2009; Phillips *et al.*, 2009). It seems likely that the CUB1 domains of the C1r and C1s molecules are responsible for binding to four of the ‘stalks’ of the C1q molecule, while the remaining two

Figure 2 A schematic representation of the classical complement pathway. The C1 complex is composed of C1q (structure of globular head domain shown (PDB identifier:1PK6)) and two molecules each of zymogen C1r (1MD7) and C1s (4JIY). The classical pathway is triggered by binding of C1q to antibody–antigen complexes. C1r autoactivates (1MD8) and then cleaves and activates C1s (1ELV), which in turn cleaves C4 (4FXG) into C4a and C4b and then C2 into C2a (2I6S) and C2b (3ERB) fragments. C4b binds covalently to the target surface and C2a coordinates with it to form an enzymatic complex termed the C3 convertase (C4bC2a).

stalks bind at the interface of the CUB1-EGF-CUB2 domains of C1r (Gingras *et al.*, 2011; Forneris *et al.*, 2012). The resting C1 complexes contain zymogens or inactive forms of the proteases, while binding of the globular heads to ligands is thought to induce further splaying of the stalks, thus inducing a ‘mechanical’ change to the position of the proteases interwoven with the stalks and so allowing C1r molecules to catalyze their autoactivation (Brier *et al.*, 2010). Activated C1r in turn catalyzes the activation of C1s.

The structures of the zymogen and activated forms of C1r (Budayova-Spano *et al.*, 2002a,b; Kardos *et al.*, 2001) and C1s (Gaboriaud *et al.*, 2000; Perry *et al.*, 2013) reveal that the C1s zymogen is particularly well regulated prior to activation, with

multiple mechanisms used to occlude the active site of the protease and thus maintain it in the inactive zymogenic state (Perry *et al.*, 2013). Recent studies have shown that the C1r active site is highly specific for the P2 Gln residue of substrates in particular (Wijeyewickrema *et al.*, 2013) and that the CCP domains of the two enzymes are important for their recognition during autoactivation and activation of C1s by C1r (Kardos *et al.*, 2008).

Once activated, C1s is responsible for the cleavage of C4 and C2. Only the catalytic module (CCP1-CCP2-SP) is required for the cleavage of its substrates (Rossi *et al.*, 1998). A positively charged exosite on the SP domain of C1s interacts with a highly negatively charged region of C4, centered upon

three sulfotyrosine residues, to effect efficient cleavage of C4 (Duncan *et al.*, 2012). The exosite on the SP of C1s is not fully formed in the zymogen form of the molecule and only switches all four positively charged residues of the region into the correct positions for binding to C4 upon activation by C1r (Perry *et al.*, 2013). Recently, the structure of MASP-2 in complex with C4 has been solved (Kidmose *et al.*, 2012) and a similar SP exosite interacting with sulfotyrosine residues on C4 has been identified. Additionally, the location of a CCP exosite at the junction of the CCP1 and CCP2 was elucidated for MASP-2. By analogy, C1s has similar residues at this position in its CCP domains (Perry *et al.*, 2013) and therefore it is likely that this CCP exosite will also be required for efficient cleavage of C4 by C1s.

C1-inhibitor or serpin G1 has been shown to be the endogenous inhibitor of both C1r and C1s (Caliezi *et al.*, 2000). The inhibitor interacts with C1r with a k_{ass} value of $1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ (Sim *et al.*, 1980) and with C1s at a slightly higher rate of $4 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ (Wuillemin *et al.*, 1997). The rate of interaction between C1r and C1-inhibitor is enhanced about 2.5-fold by heparin (Sim *et al.*, 1980), while that between C1s and C1-inhibitor is enhanced 60-fold by heparin and 130-fold by polyanions, such as dextran sulfate (Wuillemin *et al.*, 1997). The rate enhancement brought about by heparin in this context is most likely physiologically relevant, although the greater enhancement induced by non-physiological polyanions, such as dextran sulfate, suggests that other physiologically relevant cofactors that are able to bring about a greater effect are yet to be identified.

The C2 component of complement is produced as a five domain protein with a number of glycosylation sites included in its primary structure. From the N-terminus, the protein has three CCP domains, a von Willebrand factor A-type (VWA) domain and serine protease domain (Forneris *et al.*, 2012). After complexing with the C4b produced by C1s or MASP-2 cleavage, C2 is cleaved by the same enzymes to produce the C2a and C2b fragments. C2a remains bound to C4b and forms the proteolytic component of the C3 and C5 convertase complexes, while the C2b fragment has no known explicit function.

C2 activation by proteolytic cleavage is atypical relative to other serine proteases, which are generally activated by cleavage to create a new N-terminal residue, generally Ile. This new N-terminal residue binds into a hydrophobic cavity close to the active site to effect completion of the so-called oxyanion hole within the active site that is required to stabilize highly charged intermediate species formed during the catalytic cycle of the enzyme. In contrast, C2 is cleaved between its CCP3 and VWA domains, thus the serine protease domain is not activated in the 'normal' manner for serine proteases. The solution of the structure of C2a (Milder *et al.*, 2006) provided clues as to how this worked for C2a. It was found that the new N-terminus created when C2 was cleaved to form C2a nestled into a cavity within the VWA domain located close to the interface between the VWA and SP domains of C2a. This new conformation then causes a change in the active site of C2a such that the enzyme is in a conformation close to that required for catalytic competence. The authors speculated that full catalytic competence would most likely be attained following the binding of the cognate substrate (C3) to the

enzyme. Thus, the creation of the new N-terminus for this enzyme upon activation does indeed appear to be crucial to its activation. Cofactor interactions with C4b and the incoming C3 substrate are also likely to play a major role, suggestive of an enzyme with several levels of regulation and control built into its structure.

Lectin Pathway

The lectin pathway of complement activation (Figure 3) is mediated by the recognition of arrays of molecules on foreign surfaces that are not present on host surfaces. The most typical arrays recognized by molecules of this pathway are glycan arrays (Ohta *et al.*, 1990), hence the term for the pathway as a whole.

The first lectin recognition molecule discovered was mannose-binding lectin (MBL) (Kawasaki *et al.*, 1989). This molecule has been shown to be somewhat similar in architecture to the C1q molecule, with the collagen-like stalks providing attachment points for the MBL-associated serine proteases (MASPs) (Gingras *et al.*, 2011; Forneris *et al.*, 2012) and the globular heads recognizing high-mannose glycan arrays on pathogen surfaces (Turner and Hamvas, 2000). The molecule is composed of a base trimer unit, with no intrinsic ability to activate complement, with disulfide bonding furthering the assembly into higher order oligomers that have been shown to be able to efficiently activate the system. More recently, a number of other recognition molecules have been identified for this pathway, such as the three ficolin molecules and collectin-11 (Endo *et al.*, 2011; Yongqing *et al.*, 2013; Ma *et al.*, 2013). These different recognition molecules appear to allow the system to recognize an overlapping, yet diverse spectrum of pathogens and thus mediate activation of the complement system.

The MASPs have very similar domain architecture to C1r and C1s of the classical pathway, but only two genes encode the 5 proteins that are produced in this system, with gene splicing providing a mechanism to generate the protein level complexity (Yongqing *et al.*, 2012). This fact alone makes study of these molecules by 'normal' genetic manipulation of model organisms more challenging. The *MASP1/3* gene encodes three proteins (Yongqing *et al.*, 2012): MASP-1, MASP-3, and Map44. MASP-1 and MASP-3 share the same CUB1-EGF-CUB2-CCP1-CCP2 region, but differ in their SP domains, while Map44 has the same CUB1-EGF-CUB2-CCP1 domains as the two enzymes, followed by a unique 17 amino acid segment C-terminal to the CCP1 domain. The *MASP-2* gene gives rise to two proteins: MASP-2 and sMAP. Once again, sMAP is a truncated version of MASP-2, consisting of the CUB1-EGF domains of the protein. The role of the truncated versions of the MASP proteases is not clear. It has been postulated that they compete for binding to recognition molecules and thus regulate the activity of the system (Iwaki *et al.*, 2006) since they are essentially inactive in every other sense thus far tested, but their precise roles are not clear at this point. It is evident that the MASPs and their truncated versions are able to bind as homo- and heterodimers to the recognition molecules, thus giving rise to enormous complexity in the composition of these complexes in an individual.
